
Minocycline

Doxycycline

Figure 34.1 Tetracyclines and other tetracycline structures.

Resistance: Because the tetracyclines have been used over many years in veterinary and human medicine, resistance is common and occurs across all groups of bacteria. The mechanisms of acquired resistance include: (i) energy-dependent efflux of antibiotic (membrane efflux proteins), or (ii) altered target whereby the ribosome is protected from binding of tetracyclines (Chopra et al., 1992). A third mechanism whereby the drug is attacked by enzymes liberated by the bacteria is possible. The genes mediating resistance may be carried on plasmids or transposons. Resistance to one tetracycline will generally produce cross-resistance to the others in the group. One of the exceptions is for *Staphylococcus* spp., which is discussed in Section Antimicrobial Spectrum and Clinical Uses. The newest tetracycline, tigecycline, is active against many organisms (e.g., methicillin-resistant staphylococci) that are resistant to older tetracyclines (Agwuh and MacGowan, 2006).

Table 34.1 Chemical and physical properties of tetracyclines

Drug	Molecular weight	pK_a
Chlortetracycline	478.88	3.3, 7.4, 9.3
Doxycycline	462.46	7.75
Minocycline	457.48	8.25
Oxytetracycline	460.44	7.75
Tetracycline	444.43	8.3, 10.2

Susceptibility testing: For susceptibility testing, tetracycline may be used to test all others in the class (CLSI, 2013; CLSI, 2015). Specific breakpoints are also available for minocycline and doxycycline in dogs, and doxycycline in horses (Table 34.2). For veterinary isolates, the

Table 34.2 Tetracycline breakpoints for susceptibility testing. Source: CLSI, 2015.

Drug	Bacteria	Animal	S (µg/ml)	I (µg/ml)	R (µg/ml)
Tetracycline[a]	*Mannheimia haemolytica* *Pasteurella multocida* *Histophilus somni*	Cattle	≤ 2	4	≥ 8
Tetracycline[a]	*Actinobacillus pleuropneumoniae* *Pasteurella multocida* *Streptococcus suis*	Pigs	≤ 0.5	1	≥ 2
Tetracycline	*Staphylococcus pseudintermedius*	Dog	≤ 0.25	0.5	≥ 1
Doxycycline	*Staphylococcus pseudintermedius*	Dog	≤ 0.12	0.25	≥ 0.5
Doxycycline	*Staphylococcus aureus, Streptococcus equi ssp. zooepidemicus, Streptococcus equi ssp. equi, Escherichia coli*	Horse	≤ 0.12	0.25	≥ 0.5
Minocycline	*Staphylococcus pseudintermedius*	Dog	≤ 0.5	1	≥ 2
Tetracycline	Enterobacteriaceae	Human	≤ 4	8	≥ 16
Tetracycline	*Staphylococcus, Streptococcus*	Human	≤ 2	4	≥ 8

S, susceptible; I, intermediate; R, resistant.

[a] The results of tetracycline susceptibility tests are used to predict susceptibility for chlortetracycline and oxytetracycline. Isolates susceptible to tetracycline are susceptible to minocycline and doxycycline.

susceptible breakpoint varies among species and is lower than the human breakpoints, which should be considered when interpreting susceptibility tests. The breakpoint for susceptible organisms in humans is ≤4 µg/ml for all organisms, except streptococci, which is ≤2 µg/ml.

Pharmacokinetic–Pharmacodynamic Properties

Based on an evaluation of tetracycline pharmacokinetic–pharmacodynamic properties (PK-PD), the effectiveness is best expressed as a ratio of the area-under-the-curve for a 24-hour interval to the minimum inhibitory concentration (AUC_{24}/MIC) (Agwuh and MacGowan, 2006). The optimal AUC/MIC ratio is in the range of 25–40, with Andes and Craig (2007) suggesting a value of 25. In veterinary studies this has been explored insufficiently. One study (Prats et al., 2005) examined PK-PD parameters after administration of doxycycline to swine in drinking water at 10 mg/kg. They reported high AUC/MIC ratios ranging from 60 for *Pasteurella,* 155 for *Mycoplasma,* and 585 for *Bordetella*. For *Actinobacillus,* which exhibits a higher MIC, the AUC/MIC was only 13. However, these ratios did not factor the protein binding, which is at least 90% (Table 34.3). Using a fraction unbound (*fu*) value of 0.1, reduces these ratios substantially. Ideal AUC/MIC ratios from their study would be achieved only for *Bordetella bronchiseptica*.

For *Staphylococcus* isolates from dogs, substantial PK-PD analysis was performed for doxycycline and minocycline (Maaland et al., 2013, 2014; Hnot et al., 2015a). It was concluded that AUC/MIC was the parameter that should be used for analysis, and a AUC/MIC ratio of 25 of the *unbound fraction* was optimum for predicting susceptibility and deriving dosages administered.

Table 34.3 Protein binding of tetracyclines in various species (references provided in text)

Drug	Species	% Protein binding
Chlortetracycline	Cows	47–51
	Sheep	46–50
Doxycycline	Calves	92
	Cats	98
	Horses	82
	Dogs	91–92
	Pigs	93
	Sheep	84–90
	Turkeys	70–85
Oxytetracycline	Buffalo	42
	Cows	18–22
	Horses	50
	Pigs	75.5
	Sheep	21–25
	Trout	55
Tetracycline	Cows	31–41
	Sheep	28–32
Minocycline	Dog	65.8
	Sheep	80

Absorption

Tetracyclines can be administered intravenously (most tetracyclines) or intramuscularly (oxytetracycline). The oral route also has been used (Table 34.4). Although some formulations (e.g., chlortetracycline and tetracycline) have been administered in feed and water for pigs, cattle, and poultry, the systemic effects of this route of administration may be much less than anticipated. In a study in which oxytetracycline was fed to pigs (Hall et al., 1989) the authors concluded that feeding this medication at a rate of 0.55 g/kg of feed resulted in plasma concentrations so low that only highly susceptible

Table 34.4 Comparison of oral absorption of tetracyclines in animals (mean values of studies reported; references listed in text)

Drug	Species	Systemic absorption (F%)
Chlortetracycline	Chickens	1
	Turkeys	6
	Pigs	6, 11, 19 (depending on the study and fasting conditions)
Oxytetracycline	Pigs	3–5
	Fish	6
	Turkeys	9–48
Tetracycline	Pigs	5, 8, 18, 23 (depending on the study and fasting conditions)
	Dogs	40
	Cats	50
Doxycycline	Pigs	21.2
	Chickens	41.3
	Turkeys	25, 37, 41, 63.5 (depending on age)
	Horses	17.3 (intragastric); 6 as a top dressing; higher in foals
	Dogs	53 (hyclate), 33.5 (monohydrate)
	Dogs	61.85 (summary of 4 studies)
	Calves	70
Minocycline	Dogs	50.3
	Cats	62

bacteria would be inhibited, with plasma concentrations reaching only one-tenth of the MIC for most pathogens. Several studies have examined use of tetracyclines added in subtherapeutic concentrations to feed rations (in particular, chlortetracycline) (Zinn, 1993; Jones et al., 1983; Dawson et al., 1983; Williams et al., 1978; Quarles et al., 1977; Richey et al., 1977; Nivas et al., 1976). The explanation for low oral absorption is not clear, but may be multifactorial. Tetracyclines are zwitterions and ionized at physiological pH values (see Table 35.1). Although the tetracyclines are relatively lipophilic drugs, they are ionized in the gastrointestinal tract and may not cross membranes easily. The oral absorption of tetracycline can be reduced in the presence of food (Nielsen and Gyrd-Hansen, 1996; Hnot et al., 2015b). Tetracyclines can easily chelate to polyvalent cations, which decreases the absorption several-fold. Thus, tetracycline oral absorption can be decreased with the coadministration of food, dairy products, polyvalent cations (i.e., Ca^{2+}, Mg^{2+}, Fe^{2+}, Al^{3+}), kaolin/pectin preparations, iron-containing supplements, and antacids (Weinberg, 1957; Waisbren and Hueckel, 1950; Harcourt and Hamburger, 1957; Neuvonen et al., 1970; Hägermark and Hoglund, 1974; Gothoni et al., 1972; KuKanich et al., 2014; KuKanich and KuKanich, 2015). When doxycycline or minocycline were administered with sucralfate (containing aluminum) oral absorption was significantly reduced unless the sucralfate was administered 2 hours after the tetracycline (KuKanich et al., 2014; KuKanich and KuKanich, 2015).

Distribution

Once absorbed, tetracyclines bind to plasma proteins to varying degrees in each species with doxycycline being greater than 80% in most animals (Riond and Riviere, 1989b) (Table 34.3). The high protein binding for some drugs may limit the microbiologically active fraction in the plasma. For the agents that are not restricted by protein binding, tetracyclines are widely distributed throughout most tissues of the body, including intracellular sites. Tables 34.5–34.9 show the pharmacokinetic variables for some of these drugs. High protein binding can limit tissue distribution. Bidgood and Papich (2003) showed that plasma protein binding for doxycycline was high (91.75%), which drastically limited the distribution into the tissue fluid. The same property was shown with doxycycline in horses (Davis et al., 2006). The plasma protein binding of 82% in horses reduced distribution to tissue fluid. Maaland et al. (2014) showed that plasma protein binding of minocycline limited the distribution to approximately 50% of the dose administered. Protein binding has less of an effect on distribution to intracellular sites and joint fluid (see below in this section).

Tetracyclines are moderately lipophilic (depending on the pH) compared to some other classes of antibiotics (e.g., β-lactams, and aminoglycosides); therefore, for the fraction not restricted by protein binding, at physiological pH they are capable of crossing lipid membranes. Some tetracyclines penetrate tissues better than others.

For example, minocycline and doxycycline, being more lipophilic (Barza et al., 1975), penetrate brain, ocular tissues, spinal fluid, and prostate better than other tetracyclines, such as oxytetracycline or chlortetracycline. Tetracyclines are commonly reported to concentrate intracellularly, and doxycycline has a higher affinity for intracellular accumulation than other tetracyclines (Gabler, 1991; Forsgren and Ballahsene, 1985; Davis et al., 2006). In vitro analysis of the penetration of radiolabeled doxycycline into isolated human polymorphonuclear leukocytes revealed a cellular-to-extracellular concentration ratio of 13 (Forsgren and Ballahsene, 1985). In horses the ratio was 17 at peak concentrations (Davis et al., 2006). These high leukocyte concentrations may contribute to the reported antiinflammatory effects. Minocycline is found in high concentrations in the bronchial secretions (Kelly and Kanegis, 1967a; MacCulloch et al., 1974); prostate (Fair, 1974); brain (Barza et al., 1975); thyroid, saliva, and tears (Hoeprich and Warshauer, 1974). Doxycycline is distributed to the epithelial lining fluid of the airways is high with 87% penetration after an intragastric dose. Distribution into joint fluid of horses has been shown, which has implications for both treating infections of the joint, and also for controlling joint inflammation (Schnabel et al., 2010, 2012; Maher et al., 2014). Distribution of

Table 34.10 Formulations of tetracyclines used in animals

Formulations approved by US FDA for animals
Oxytetracycline hydrochloride soluble powder: added to drinking water for poultry, cattle, pigs
Oxytetracycline for medicated feed: added to feed for cattle, poultry, fish, pigs
Oxytetracycline tablets: oral treatment for calves
Oxytetracycline injection: IM injection for cattle and pigs. These products are occasionally used in horses and other species. There is both a conventional and long-acting formulation. The long-acting formulation contains a viscosity excipient used to prolong the absorption from the injection site
Tetracycline bolus: oral treatment for cattle
Tetracycline hydrochloride soluble powder: added to drinking water for cattle, pigs and poultry
Tetracycline oral suspension: oral treatment for cats and dogs
Chlortetracycline hydrochloride soluble powder: added to drinking water for poultry, calves, and pigs
Chlortetracycline for medicated feed: premix added to feed for pigs, cattle, poultry
Formulations approved for humans, but used off-label in animals
Doxycycline capsules and tablets: used in dogs, cats, birds, horses, and some exotic animals
Minocycline capsules, tablets, and injectable solution used in dogs, cats, and horses

doxycycline and minocycline to equine joint fluid was 4.6 times, and 2 times the plasma concentrations for doxycycline and minocycline, respectively.

Metabolism, excretion, and elimination

The elimination rates and half-lives are presented in the pharmacokinetic tables for each drug and various species (Tables 34.5–34.9). Although it varies considerably from species to species, the half-life is long enough for once or twice-daily administration in most animals. The intramuscular administration of formulations that contain viscosity excipients (e.g., 2-pyrrolidone) (Table 34.10) may prolong the terminal half-life because of a "flip-flop" effect. This is discussed in more detail in Section Oxytetracycline.

A high percent of the administered dose is eliminated in the urine via glomerular filtration, with the rest eliminated in the feces. The high concentrations in the urine can be effective for treatment of urinary tract infections caused by susceptible bacteria.

An examination of Tables 34.5–34.9 indicates that systemic clearance is similar to, or somewhat higher than GFR. Tetracyclines are also excreted in the bile, with up to 20 times the plasma concentration of tetracyclines being present in the bile (Kunin and Finland, 1961; Schach von Wittenau and Twomey, 1971).

Antimicrobial Spectrum and Clinical Uses

The use and dosages of specific agents in this group are discussed in this chapter for each drug. The value of the tetracyclines is their activity against susceptible gram-positive and gram-negative bacteria, as well as other atypical pathogens transmitted by ticks and other parasites, and blood-borne pathogens.

Tetracyclines in general have good or moderate activity against the respiratory pathogens listed in Table 34.2, but resistance can occur. Tetracyclines are usually active against *Bacillus* spp., *Corynebacterium* spp., *Erysipelothrix rhusiopathiae, Listeria monocytogenes,* streptococci, *Actinobacillus* spp., *Leptospira* spp., *Actinomyces* spp., and some anaerobes. The family Rickettsiaceae includes *Rickettsia* and *Ehrlichia,* and tetracyclines, particularly doxycycline, are considered the first drug of choice for these infections.

In birds, doxycycline is the drug of choice for treatment of *Chlamydophila psittaci* (formerly called *Chlamydia psittaci*). Tetracyclines are also useful against organisms that lack a cell wall, which would ordinarily be resistant to β-lactam antibiotics, for example, *Mycoplasma*, as well as other Mycoplasma organisms such as *Mycoplasma haemofelis* (formerly called *Haemobartonella felis*).

Resistance is common among *Enterococcus* species and members of the family Enterobacteriaceae (*Enterobacter* spp., *E. coli, Klebsiella* spp., *Proteus* spp., *Salmonella* spp.), and treatment should not be considered without a susceptibility test. Anaerobes (such as *Bacteroides* spp. and *Clostridium* spp.) have shown variable susceptibility. Commonly resistant to the tetracyclines are those infections involving *Mycobacterium* spp., *Proteus vulgaris, Pseudomonas aeruginosa,* and *Serratia* spp. Most *Streptococcus* spp. are susceptible, as are many *Staphylococcus* spp.; however, resistance can occur and a susceptibility test is advised before administering a tetracycline (e.g., doxycycline, minocycline) for treating staphylococcal infections in animals. Activity of minocycline against methicillin-resistant *Staphylococcus* has been shown. Staphylococci develop resistance through the efflux pump mediated by the gene *tetK.* These bacteria will be resistant to the other tetracyclines, including doxycycline, but not minocycline, which can still be used to treat some of these resistant infections (Hnot et al., 2015a; Weese et al., 2013; Maaland et al., 2014).

One of the clinical uses that has become common is administration of doxycycline in combination with other agents for treatment of canine heartworm disease. Tetracyclines, particularly doxycycline, are considered the first drug of choice for these infections. The *Rickettsia*-like organism found in heartworms, *Wolbachia*, is susceptible to tetracyclines, which have been used as adjunctive treatment for heartworm disease. Many filarial nematodes, such as heartworm, have a symbiotic relationship with obligate intracellular bacteria belonging to the genus *Wolbachia (Rickettsiales*). Treatment with doxycycline reduces *Wolbachia* numbers in all stages of heartworms and improves outcomes and decreased microfilaremia in dogs treated for heartworm disease. The American Heartworm Society recommends treatment with doxycycline in dogs diagnosed with heartworm disease. Preferably, it should be administered prior to treatment with an adulticide (melarsomine) at a dose of doxycycline of 10 mg/kg twice daily for 4 weeks. If doxycycline is not available, minocycline can be used as a substitute. In one assay, minocycline had better activity against *Wolbachia* than either doxycycline or rifampin (Townson et al., 2006).

Adverse Effects and Interactions

Interactions: Calcium-containing products or other di- or trivalent cations (Mg^{2+}, Fe^{2+}, Al^{+3}) will chelate with tetracyclines and interfere with oral absorption. Doxycycline is less susceptible to this interaction as calcium chelation is 19% for doxycycline but 40% and 36% for tetracycline and oxytetracycline, respectively (Barza et al., 1975). Interactions that affect oral absorption were discussed earlier in Section Absorption.

Gastrointestinal microflora changes: In horses the oral administration of oxytetracycline has been associated with proliferation of *Clostridium perfringens* or *Salmonella* in the colon, which has led to enteritis. This syndrome has been called *Colitis-X*. A more detailed discussion of the effects of tetracyclines in horses was reviewed by Papich (2003a, 2003b).

Esophageal lesions: Doxycycline entrapped in the esophagus from a broken tablet or incompletely dissolved capsule can cause injury to the esophagus and stricture. It has been demonstrated that, in cats, administration of a capsule or broken tablet can be lodged in the esophagus unless followed by some water. Therefore, one should be cautious about giving oral doxycycline medications to cats. This problem has been primarily associated with doxycycline hyclate (the form most common in the USA), rather than doxycycline monohydrate.

Problems in young animals: Tetracyclines bind to bone and teeth. They may produce teeth discoloration and inhibit growth of long bones in young animals or the offspring of pregnant animals treated with tetracyclines. The true incidence of this problem is not known in veterinary medicine, but in human medicine, tetracyclines are avoided in children less than 7 years of age (before tooth eruption). Tooth discoloration is determined by the duration of treatment rather than the dose. The discoloration is related to the chelation of tetracyclines to the calcium deposits in the developing teeth in the dentin (where it is mostly visible) and to a lesser extent in the enamel (Hamp, 1967; Hennon, 1965; Finerman and Milch, 1963; Moffitt et al., 1974). Exposure to sunlight is also important for this reaction. Although the occurrence of this in animals has not been well documented, it is prudent to avoid tetracyclines in animals during time of teeth development. The effects on bones are probably only important with high doses.

Renal tubular necrosis: Acute kidney injury has been associated with high doses and prolonged administration of oxytetracycline to ruminants (Riond and Riviere, 1989a) and dogs (Stevenson, 1980). When high doses are administered, the drug vehicle (such as propylene glycol) has been suspected to contribute to kidney effects.

Using outdated formulations: It often is stated in publications that kidney injury may occur when outdated tetracyclines are administered. The degradation products of the tetracyclines have been found to be nephrotoxic and are formed in the presence of heat, low pH, and moisture (Cleveland et al., 1965; Teuscher et al., 1982; Lowe and Tapp, 1966; Riond and Riviere, 1989a). Although we do not advocate administering outdated products, this problem does not occur with currently available formulations because the citric acid excipient is no longer used.

Hepatic disease: Idiosyncratic toxic hepatitis is possible (Böcker et al., 1982; Hopf et al., 1985). Drug-induced hepatitis has been described in people, and pregnant women appear to be at the greatest risk. The significance of hepatic reactions in veterinary medicine is unknown, but may be important at high doses.

Allergy: Hypersensitivity and drug fever have been reported. Cats appear to be more prone to drug fever from tetracyclines than other animals.

Photosensitivity: This is a direct toxic effect that damages cutaneous membranes when exposed to light. This reaction is rare in animals, but rather common in people. The incidence appears to be highest with doxycycline and demeclocycline.

Risks from IV administration: Tetracyclines administered intravenously rapidly can cause hypotension and collapse (McPherson et al., 1974; Wivagg et al., 1976; Gyrd-Hansen et al., 1981). In one study, a fast IV administration (60 seconds or less) to cattle caused collapse in 50% of the animals. Affected animals had low blood pressure, low heart rate, and ECG abnormalities. Collapse from IV injection has been prevented when the cattle were premedicated with calcium borogluconate, indicating that tetracycline may decrease the amount of

Table 34.11 Clinical dosages used for tetracyclines in animals – most frequently cited on product labels, CLSI susceptibility tables (CLSI, 2015), or in reputable references based on a consensus of the literature or pharmacokinetic studies

Drug	Species	Dose
Doxycycline	Dogs and cats	5 mg/kg q 12 h oral
Doxycycline	Horses	10–20 mg/kg q 12 h oral (never administer IV) The higher dose of 20 mg/kg will more consistently reach therapeutic targets
Oxytetracycline	Calves, cattle, and pigs	22 mg/kg q 24 h added to drinking water or in feed
Oxytetracycline	Calves, cattle	6.6–11 mg/kg q 24 h, IM
Oxytetracycline	Calves, cattle	20 mg/kg q 24 h, IM or SC; extra-label doses have been as high as 40 mg/kg
Oxytetracycline	Pigs	6.6–11 mg/kg q 24 h IM; doses as high as 20 mg/kg IM, q 24 h are also used
Oxytetracycline	Horses	10 mg/kg q 24 h, IM, or IV (slowly) (IM injections can cause pain)
Oxytetracycline	Dogs, cats	20 mg/kg, q 12 h, oral
Oxytetracycline	Sea turtles	40 mg/kg IM, followed by 20 mg/kg q 72 h, IM
Tetracycline HCL	Calves	11 mg/kg q 12 h PO
Minocycline	Horses	4 mg/kg q 12 h, PO
Minocycline	Dogs	5 mg/kg, oral, q 12 h (10 mg/kg can be considered for some organisms, but is more likely to produce vomiting)
Minocycline	Cats	8.8 mg/kg, oral, once daily (or 50 mg per cat, once daily)

calcium available to the heart for its role in contraction to the point of producing collapse of the animals.

The vehicle (solvent) used to administer tetracyclines may be responsible for adverse events. In calves, Gross et al. (1981) studied the cardiovascular effects of both oxytetracycline and the different vehicles used for injection (propylene glycol, saline, polyvinylpyrrolidine). They determined that the cardiovascular adverse effects were caused by the vehicles used and not oxytetracycline. The propylene glycol vehicle studied resulted in increased pulmonary arterial pressures and a decrease in cardiac output and stroke volume. Aortic pressure and heart rates were also depressed in association with the vehicle. They concluded that the cardiovascular effects observed were caused by endogenous release of histamine after propylene glycol injection, and this histamine release was not dependent on the animal being sensitized prior to exposure. No discernible cardiovascular effects were observed after injection with the oxytetracycline–saline combination, while the polyvinylpyrrolidine preparation and vehicle resulted in higher aortic pressure, heart rate, and overall systemic resistance.

Tetracycline has been reported to induce anaphylactic shock in dogs after intravenous injection (Ward et al., 1982) as well as possibly increasing alanine transaminase activity in the cat (Kaufman and Greene, 1993). Although there are warnings about administration of minocycline intravenously in humans, it has been administered to dogs and cats over a 5-minute interval without complication (Tynan et al., 2015; Maaland et al., 2014).

The most serious concern is intravenous injection of doxycycline in horses, which can be fatal (Riond et al., 1989a, 1992). IV administration of doxycycline to horses has caused sudden death, most likely caused by a cardiac arrhythmia. Oral administration of doxycycline to horses has not produced this problem (Davis et al., 2006).

Commonly Used Tetracyclines

Chlortetracycline

Chlortetracycline was the first tetracycline discovered and was first introduced for clinical use in 1948 (Figure 34.1). The use of chlortetracycline has mostly been confined to administration in feed and water to livestock. It has low oral absorption and the effects are likely caused by local effects in the intestine for weight gain. As mentioned earlier, production uses of tetracyclines for weight gain and improved feed efficiency have been phased out by an FDA guidance taking effect in 2017. Chlortetracycline is not utilized to any significant degree in small-animal or equine medicine. Doses for other animals are listed in Table 34.11. Because the therapeutic use has declined, the value of chlortetracycline has diminished. The reader is referred to earlier editions of this book for more detailed information about its past use.

Chlortetracycline has been used in pigs as a feed additive for the treatment of *Salmonella typhimurium* (Jones et al., 1983; Williams et al., 1978), coccidiosis (Onawunmi and Todd, 1976), and many other porcine diseases. Similar infections have been treated with chlortetracycline in poultry (Fagerberg et al., 1978; Nivas et al., 1976; Quarles et al., 1977; Landgraf et al., 1981; Dawson et al., 1983). Chlortetracycline has been reported to decrease the breeding rate of sows, although it did increase conception and farrowing rates. Birth weights, overall litter weights of pigs born alive, and weights of pigs at weaning were also significantly higher than unmedicated controls (Soma and Speer, 1975).

Tetracycline

The use of tetracycline (Figure 34.1) is more limited today because other forms are used in livestock (e.g., oxytetracycline) or in horses and small animals (minocycline, doxycycline). Relatively little has been published in recent years on tetracycline and previous editions of this book may be consulted for older information. Some pharmacokinetic information on tetracycline is available in Table 34.6.

There are still approved formulations of tetracycline for small animals. These forms are occasionally used to treat various diseases such as *Rickettsia rickettsii* (Rocky Mountain spotted fever) when doxycycline is not available. A study by Breitschwerdt et al. (1991) determined that tetracycline, chloramphenicol, and enrofloxacin were all equally effective in treating this disease in experimentally infected dogs. Tetracycline was also found to be efficacious in the treatment of canine ehrlichiosis (*E. canis*) (Amyx et al., 1971; Davidson et al., 1978). However, it was less effective at clearing ehrlichiosis in dogs compared to imidocarb dipropionate (Price and Dolan, 1980).

Oxytetracycline

The most commonly used tetracycline in food animals is oxytetracycline (Figure 34.1). The most complete pharmacokinetic analysis was performed by the Food Animal Residue Avoidance Databank (Craigmill et al., 2004) for oxytetracycline in cattle. This analysis was derived from 41 data sets and 25 published papers (489 data points). A metaanalysis of this data from a dose of 20 mg/kg IM of long-acting tetracycline yielded the following population data: half-life 21.6 hours, peak concentration (C_{max}) 5.61 μg/ml, clearance 0.115 l/kg/h, and volume of distribution per fraction absorbed (Vd/F) 3.34 l/kg. Other pharmacokinetic values are shown in Table 34.7. Doses are listed in Table 34.11.

The clinical usefulness of oxytetracycline has been documented in most domestic species of animals, and previous editions of this textbook should be consulted for historic work on oxytetracycline. Oxytetracycline has been a common treatment for lung infections associated with bovine respiratory disease (BRD). Although the in vitro susceptibility may not always be favorable (Table 34.2), oxytetracycline may accumulate in pneumonic lung preferentially over normal lung, and an increased volume of distribution has been shown in diseased animals, which may improve treatment outcome (Ames et al., 1983, 1985; Baxter and McKellar, 1990). Tissue levels are maintained for 24 hours after dosing. Other uses for cattle have included treating cases of *Moraxella bovis*/infectious bovine keratoconjunctivitis infections in calves (Smith and George, 1985; George and Smith, 1985; George et al., 1985, 1988), mastitis, and anaplasmosis. Although oxytetracycline has been used as an intrauterine infusion for cows with retained fetal membranes, this practice has been discouraged (Dinsmore et al., 1996). Intrauterine use in cows may not improve reproductive performance in cows with retained fetal membranes and may cause illegal residues in milk of dairy cows (Dinsmore et al., 1996; Stevens et al., 1995).

Oxytetracycline has been used to treat ehrlichiosis in dogs (Adawa et al., 1992) as an alternative to doxycycline. However, the use of oxytetracycline in small animals is limited because of a lack of convenient dose forms and greater use of doxycycline and minocycline.

In horses oxytetracycline is sometimes administered for treatment of Potomac horse fever (*Neorickettsia risticii*) (Palmer et al., 1992). Larson and Stowe (1981) reported high serum concentrations obtained in clinically normal horses given 10 mg/kg oxytetracycline intravenously, with serum concentrations peaking at 30 minutes postinjection (16.85 μg/ml) and high concentrations persisting through at least 240 minutes (4.67 μg/ml). Oxytetracycline penetrated well into pulmonary and renal tissue, as well as into bronchial fluid. In another study of oxytetracycline in horses, Brown et al. (1981) used a dose of 5 mg/kg intravenously and found a peak concentration of oxytetracycline in the serum at 0.5 hours after dose, with a steady decline in serum levels through 36 hours. Similar fluid concentration versus time profiles were also demonstrated for oxytetracycline detected in the synovial fluid, peritoneal fluid, and urine after intravenous injection, suggesting that oxytetracycline crosses those membranes easily and that the concentrations obtained would be adequate for combating such infections as *Corynebacterium equi, Streptococcus zooepidemicus,* and *Actinobacillus* spp., but with limited efficacy in treating some *Staphylococcus aureus, Escherichia coli,* and *Salmonella* spp., and no efficacy in treating common *Pseudomonas aeruginosa* pathogens.

The pharmacokinetic features of oxytetracycline for some species are shown in Table 34.7. Data on the pharmacokinetics of oxytetracycline is available for dogs (Baggot et al., 1977; Cooke et al., 1981), calves (Burrows et al., 1987; Banting et al., 1985; Banting and Baggot, 1996; Schifferli et al., 1982; Meijer et al., 1993a, 1993c; TerHune and Upson, 1989; Toutain and Raynaud, 1983), ponies and donkeys (Horspool and McKellar, 1990), horses (Larson and Stowe, 1981; Brown et al., 1981; Teske et al., 1973), foals (Papich et al., 1995), chickens (Black, 1977), swine (Nielsen and Gyrd-Hansen, 1996; Hall et al., 1989; Pijpers et al., 1990; Mevius et al., 1986b), sheep (Immelman and Dreyer, 1986), elephants

(Bush et al., 2000), fish (Black et al., 1991; Grondel et al., 1989), and other species (Teare et al., 1985; Martinsen et al., 1992; McElroy et al., 1987; Kirkwood et al., 1988). Oxytetracycline is relatively well behaved from a pharmacokinetic perspective, which allows easy extrapolation across species. A physiological based pharmacokinetic model was developed, which allowed extrapolation of oxytetracycline from dogs to humans after intravenous or oral administration (Lin et al., 2015).

Oxytetracycline is the most common injectable tetracycline for reptiles. The elimination of oxytetracycline from reptiles is slow, which allows for infrequent dose intervals. Harms et al. (2004) showed that the half-life in sea turtles was over 60 hours, which would allow for extended-interval dosing (41 mg/kg once IM, followed by 21 mg/kg every 72 hours IM). In another study, Helmick et al. (2004), showed that in alligators the half-life of oxytetracycline was 74 hours, which allows for long intervals between doses (for example every 5 days).

Oxytetracycline solution in propylene glycol is 50–100 mg/ml (Oxy-Mycin®, Terramycin, Oxy-Tet®), and is available as a solution in povidone (IM use only). A "long acting" preparation is available with the viscosity excipient 2-pyrrolidone (200 mg/ml) in formulations such as Liquamycin® LA-200. Absorption of oxytetracycline is known to vary with injection site in calves. A report by Nouws and Vree (1983) found that site-to-site intramuscular injection bioavailability varied widely at 52 hours postinjection, with bioavailability being 79% in the buttock, 86% in the neck, and 98% in the shoulder.

Administration of the long-acting formulation, particularly in food animals, is intended to prolong serum and tissue concentrations for long periods of time – usually every 48 hours, but may be up to 3–5 days for some pathogens. Several studies have described the pharmacokinetic patterns of the conventional and long-acting formulations in dogs, sheep, cattle, and pigs. Toutain and Raynaud (1983) examined the pharmacokinetic parameters of oxytetracycline with the 2-pyrrolidone carrier (long-acting formulation) injected intramuscularly in young beef cattle. This intramuscular formulation resulted in rapid development of serum concentrations of 4 μg/ml within 60–90 minutes, followed by persistence of these levels for approximately 12 hours. Serum half-life was calculated to be 21.8 hours, and bioavailability was 51.5%. Serum concentrations exceeding 0.5 μg/ml were found to persist for approximately 87 hours, in contrast to approximately 52 hours for the conventional formulation in another study using cattle (Mevius et al., 1986a). Davey et al. (1985) injected cattle with the conventional oxytetracycline hydrochloride or the long-acting formulation, both at a standard 20 mg/kg dose, and found that although the long-acting formulation had lower peak serum concentrations when compared to the conventional formulation, the long-acting formulation had a longer serum half-life (36.9 hours) than the conventional formulation (11.1 hours). In addition, the time it took for serum concentrations to drop below 0.5 μg/ml was 86.8 hours for the long-acting formulation and 51.5 hours for the conventional formulation. Similar findings have been reported for dairy cows (Nouws et al., 1985b), calves (Nouws and Vree, 1983), pigs (Nouws et al., 1990; Xia et al., 1983; Nouws, 1984; Banting and Baggot, 1996), dogs (Immelman and Dreyer, 1981), and sheep (Nouws et al., 1990).

Despite the advantages of the long-acting oxytetracycline formulation cited above, there are also studies that cast doubt on the value of a long-acting formulation. In one such study, the long-acting oxytetracycline (in 2-pyrrolidone) was compared to a conventional formulation in pigs at a dose of 20 mg/kg of each formulation (Hall et al., 1989). There was no difference in area-under-the-curve (AUC) or disappearance rate constant from either formulation. The authors concluded that the long-acting formulation did not provide an advantage for pigs.

Doxycycline

The most popular drug in this class for small animals and birds is doxycycline (Figure 34.1). It is available in two forms, doxycycline hyclate and doxycycline monohydrate. Doxycycline hyclate (a dimer of two molecules) has been used more commonly but the monohydrate also is available. Doxycycline hyclate (Vibra-Tabs, and Vibramycin) is available in tablets and capsules. There is also a flavored doxycycline calcium suspension and monohydrate suspension for people. Doxycycline hyclate tablets (Ronaxan) is approved for dogs and cats in some countries, and doxycycline monohydrate (VibraVet) approved in other countries. There are no reported differences between these two formulations with respect to oral absorption, but the hyclate form is associated with more injury to the esophagus (see Section Adverse Effects and Interactions). Doxycycline hyclate (Vibramycin IV) also can be administered IV to patients (except horses) that cannot tolerate oral medications. The IV formulation is reconstituted before use and is stable for only 12 hours following reconstitution (72 hours in refrigerator, 8 weeks in the freezer).

Doxycycline and minocycline (discussed in Section Minocycline) differ from tetracycline, oxytetracycline, and chlortetracycline in that they are more lipophilic (five- to tenfold increase), resulting in higher tissue penetration, higher intracellular penetration, larger volumes of distribution, and better overall antimicrobial properties (Barza et al., 1975).

The pharmacokinetics of doxycycline has been studied in dogs and cats (Wilson et al., 1988; Riond et al., 1990; Bidgood and Papich, 2003), pigs (Riond and Riviere, 1990a, 1990b; Prats et al., 2005), calves (Meijer et al., 1993b; Riond et al., 1989b), goats (Jha et al., 1989), rhesus monkeys (Kelly et al., 1992), horses and foals (Davis et al., 2006; Papich et al., 1995; Winther et al., 2011), and birds (Flammer et al., 2001, 2003; Powers et al., 2000; Prus et al., 1992; Greth et al., 1993). Some of the pharmacokinetic data for doxycycline for commonly encountered species of animals are listed in Table 34.8. Oral absorption was reported for various species (Table 34.4) and shown to be higher than for other tetracyclines. Doses are listed in Table 34.11.

High intracellular drug concentrations produce good activity against intracellular pathogens. Doxycycline is the first drug of choice for treatment of tick-borne infections caused by *Ehrlichia canis* and *Rickettsia,* as well as *Mycoplasma haemofelis* (formerly called *Haemobartonella felis).* Efficacy of doxycycline for rickettsial disease in animals was demonstrated by Breitschwerdt et al. (1997, 1999). The most common dose for dogs and cats is 5 mg/kg q12 h orally (25 mg/cat q12 h). It also has been considered one of the treatments of choice, in addition to azithromycin, for treatment of infections caused by *Bartonella* (Kordick et al., 1997; Brunt et al., 2006), although the most appropriate drug for *Bartonella* is still unknown (Brunt et al., 2006). The role of doxycycline for treatment of canine heartworm disease was discussed in Section Antimicrobial Spectrum and Clinical Uses. The effectiveness is attributed to the activity against the symbiont *Wolbachia.*

Doxycycline has also been used for infections in other species, including respiratory tract disease and systemic colibacillosis in poultry (Migaki and Babcock, 1977; George et al., 1977) and anaplasmosis in splenectomized calves (Kutter and Simpson, 1978).

An important use of doxycycline is in birds. Doxycycline has become a treatment of choice for psittacosis caused by *Chlamydophila psittaci* (formerly called *Chlamydia psittaci*) in birds because of its good oral absorption, tolerance, and efficacy (Flammer et al., 2001, 2003; Powers et al., 2000). The oral route is preferred for doxycycline because IM injections cause pain and tissue irritation and did not maintain therapeutic concentrations. Oral doxycycline can be administered to pet birds by simply adding doxycycline hyclate to drinking water. When doxycycline hyclate was added to drinking water at concentrations of 0.28 mg/ml and 0.83 mg/ml (280 and 830 mg/l), plasma concentrations in treated birds were maintained high enough for susceptible organisms during a 45-day treatment (Powers et al., 2000). Another study confirmed that when added to drinking water at a concentration of 0.8 mg/ml (800 mg/l) it produced effective concentrations in psittacine birds for a treatment duration of 42 days (Flammer et al., 2001). Lower water concentrations of 400 mg/l also may produce effective concentrations in some birds.

Minocycline

The administration of minocycline (Figure 34.1) is considered when doxycycline is not available, or an alternative is needed. Like doxycycline, it is more lipophilic than other tetracyclines (Barza et al., 1975) and generally has good oral absorption. Pharmacokinetics have been studied in dogs, cats, and horses and presented in Table 34.9. Doses are listed in Table 34.11.

Minocycline has been well tolerated, but as the dose is increased in dogs from 5 mg/kg to 10 mg/kg, more vomiting is expected. Intravenous administration has been tolerated in cats and dogs if administered slowly over 5 minutes (Tynan et al., 2015; Maaland et al., 2014). A toxicological study performed by Noble et al. (1967) examined the use of minocycline in Beagles administered a daily dose of 5, 10, 20, or 40 mg/kg intravenously for 1 month. Adverse effects occurred only in the high dose groups. Minocycline produced erythema of the skin and mucous membranes, characterized by papules around the eyes, muzzle, ears, and abdomen; the intensity of these lesions was directly proportional to the dose administered. Decreases in red blood cell packed cell volumes, hemoglobin concentrations, and red cell counts were noted in dogs receiving 10 mg/kg or more of minocycline intravenously. Similar adverse effects were noted by Wilson et al. (1985). Other toxicological studies with minocycline have been performed in dogs, rats, mice, and monkeys (Benitz et al., 1967).

Tissue distribution studies in dogs were reported by Maaland et al. (2014). After oral administration distribution to tissue fluids is approximately 50% of the plasma drug concentration. After a dose of 4 mg/kg oral to horses there was good penetration to equine joints (Schnabel et al., 2012). Minocycline appears to be minimally metabolized (Wilson and Green, 1986), but metabolism data are not available for all species. Systemic clearance values in dogs and cats suggest that glomerular filtration plays an important role in elimination (Tynan et al., 2015; Maaland et al., 2014).

Other Nonantimicrobial Uses of Tetracyclines

Tetracyclines also have been used as immunomodulating drugs and antiinflammatory drugs. This use of tetracyclines has focused on treatment of osteoarthritis, vasculitis, and dermatitis.

Dermatology

A review is available of the uses of tetracyclines in dermatology by Tsankov et al. (2003). The action of tetracyclines appears to be via inhibition of inflammatory cell infiltration. Tetracyclines also may affect cyclooxygenase (COX-2) mediated prostaglandin (PGE-2) synthesis during inflammation. The antiinflammatory activity was reviewed by Suomalainen et al. (1992). The combination of tetracycline and niacinamide has been used in dogs for the treatment of discoid lupus erythematosus, pemphigus foliaceus, ulcerative dermatosis of Collies and Shetland Sheepdogs (vesicular cutaneous lupus erythematosus), lupoid onychodystrophy, and sterile pyogranulomatous disease (including sterile nodular panniculitis) (Auxilia et al., 2001; Rothstein et al., 1997; White et al., 1992). The exact mechanism to explain the efficacy of this combination is uncertain, but some inflammatory mechanisms are probably important. However, as an antipruritic treatment, this combination is not impressive (Beningo et al., 1999).

Alone, tetracyclines have been used for conditions in which an antiinflammatory mechanism may play a role (Suomalainen et al., 1992). Doxycycline was used in one study of plasmacytic pododermatitis in cats (Bettenay et al., 2001). Remission of signs occurred in 26% of cats.

Angular Limb Deformities in Foals

Another use of oxytetracycline has been the administration of high doses to newborn foals for the purpose of correcting angular limb deformities (Madison et al., 1994; Kasper et al., 1995). The doses have been as high as 50–70 mg/kg, IV, q 48 h. The explanation for this effect of oxytetracycline in horses may be explained by the relaxation of tendons. In rats, oxytetracycline is known to decrease viscoelastic properties of tail tendons in young animals (Wintz et al., 2012). The pharmacokinetics in foals at this dose and adverse effects were explored by Papich et al. (1995) and no adverse effects were reported.

Arthritis

Both in vivo and in vitro studies have documented antiinflammatory, chondroprotective, and antiarthritic effects of tetracyclines, particularly doxycycline and minocycline. These studies have been summarized (Schnabel et al., 2010, 2012; Maher et al., 2014; Haerdi-Landerer et al., 2007). The effects on arthritis may be caused by decreased inflammatory mediators, such as prostaglandins, and the reduced matrix metalloproteinases (MMP). In calves, the predominant effect was lower activity of MMP. In horses, these effects may be possible even after administration of a low dose that produces concentrations below the MIC of bacteria (Maher et al., 2014).

Yu et al. (1992) indicated that doxycycline administered prophylactically markedly reduced the severity of osteoarthritis in dogs with surgically induced transactions of the anterior cruciate ligament. Inhibition of classical lesions in that model was felt to be due to doxycycline's ability to inhibit (chelate) metalloproteases (collagenase, gelatinase, stromelysin) in the degenerating cartilage of the canine knee.

Aminoglycoside Antibiotics

Mark G. Papich and Jim E. Riviere

Aminoglycoside antibiotics have been used in veterinary and human medicine for many years and have retained their importance for treating serious and routine infections. They are particularly valuable for treating infections caused by gram-negative bacilli, including bacteria that may be resistant to other agents. Their therapeutic importance derives from the rapid bactericidal effects, pharmacokinetics derived from a large variety of animal species, and relatively low rate of resistance. These advantages must be weighed against their potentially toxicity, requirement for administration by injection for systemic use, and high potential to produce chemical residues in food-producing animals.

Pharmacology of Aminoglycosides

General Properties

Aminoglycosides include the familiar drugs gentamicin, amikacin, kanamycin, and tobramycin. They also include less familiar drugs such as neomycin, dihydrostreptomycin, and paromomycin. Spectinomycin has been included with aminoglycosides in some textbooks, but we have instead included it with the miscellaneous antibiotics in Chapter 36. Aminoglycosides are a class of antimicrobial compounds produced from strains of *Streptomyces* spp. or *Micromonospora* spp. fungi. Those produced from *Streptomyces* are spelled with "mycin" and those produced from *Micromonospora* are spelled with "micin". Chemically, they are aminocyclitols: hydroxyl and amino or guanidine substituted cyclohexane with amino sugars joined by glycosidic linkages to one or more of the hydroxyl groups. These molecules have excellent solubility in water but poor lipid solubility, and are thermodynamically stable over a wide range of pH values and temperatures (Lancini and Parenti, 1982; Leitner and Price, 1982; Nagabhusban et al., 1982; Pechere and Dugal, 1979). They are large molecules with molecular weights ranging from 450 to 585. The aminoglycosides are basic polycations with pK_a values that range from 7.2 to 8.8 (Ziv and Sulman, 1974; Katzung, 1984; Prescott and Baggot, 1988).

The chemical structure of gentamicin is shown in Figure 35.1. A search for gentamicin reveals several products that have been identified (e.g., gentamicin C_1, C_2, C_{1A}, A_2, and A_3). The commercially available form contains a complex of gentamicin C_1, C_2, and C_{1A} as sulfate salts in a mixture. The proportion of each compound in a gentamicin complex can vary among commercial products. The other commonly used aminoglycosides are shown in Figure 35.2 Amikacin is a semisynthetic form synthesized from kanamycin to increase antimicrobial activity. The various mechanisms of nephrotoxicity (binding to proximal tubule brush-border vesicles and phospholipids, inhibition of mitochondrial function, etc.) may be associated with the number of free amino groups on the aminoglycoside molecule. In general, the most ionized aminoglycosides (i.e., neomycin, with six groups) are more toxic and show greater binding affinity than the least ionized aminoglycosides of the class (i.e., streptomycin, with three groups) (Bendirdjian et al., 1982; Cronin, 1979; Feldman et al., 1981; Humes et al., 1982; Just and Habermann, 1977; Kunin, 1970; Lipsky and Lietman, 1982; Luft and Evan, 1980a, 1980b; Weinberg et al., 1980). Other structural characteristics may account for differences in toxicity within groups of drugs with similar total ionization potentials (i.e., netilmicin, tobramycin, amikacin, and gentamicin, all with five ionizable groups).

Mechanism of Action

Aminoglycosides exert their antibacterial action by irreversibly binding to one or more receptor proteins on the 30S subunit of the bacterial ribosome and thereby interfering with several mechanisms in the mRNA translation process. These include disrupting an initiation complex between the mRNA and the 30S subunit, blocking further translation and thereby causing premature chain termination, or causing incorporation of an incorrect amino acid in the protein product. Although most antimicrobials that interfere with ribosomal protein synthesis are

bacteriostatic, aminoglycosides are bactericidal. Because of irreversible binding, significant postantibiotic effects can be observed.

The mechanism of bacterial penetration by the aminoglycoside through the cell membrane is biphasic. Aminoglycosides diffuse through the outer membrane of gram-negative bacteria through aqueous channels formed by the porin proteins. Once in the periplasmic space, an oxygen-requiring process transports the drug into the cell, where it interacts with the ribosome. Anaerobic bacteria are therefore resistant to the antibacterial effects of aminoglycosides. The oxygen-dependent transport is linked to an electron transport system, which causes the bacterial cytoplasm to be negatively charged with respect to the periplasm and external environment.

An additional mechanism is independent of ribosomal binding. These agents are positively charged by virtue of their amino groups (Figures 35.1 and 35.2). These agents disrupt the cell surface biofilm, particularly on gram-negative bacteria, to produce disruption, loss of cell wall integrity, and a rapid bactericidal effect. Magnesium and calcium are important to cross-bridge adjacent lipopolysaccharide molecules. Aminoglycosides competitively displace Ca^{++} and Mg^{++} and destabilize the bacteria outer membrane. Therefore, rapid death of the bacteria can be caused by a cell surface effect rather than inhibition of the ribosome. This helps explain the concentration-dependent effect and rapid bactericidal action that is a feature of aminoglycosides. This property is not as prominent for gram-positive bacteria unless administered with a cell-wall disrupting agent such as vancomycin or a β-lactam antibiotic.

The positively charged aminoglycosides also affect the accumulation in bacteria. Because of the positive charge, they are attracted electrostatically into the bacterial cytoplasm. Some divalent cations (such as Ca^{++} and Mg^{++}) are competitive inhibitors of this transport system. This proton-motive force also functions in the lysosomes and mitochondria in which aminoglycosides accumulate and may also be a factor in the intralysosomal accumulation of the aminoglycosides.

A characteristic of aminoglycoside activity is that bacterial killing is concentration-dependent, and a postantibiotic effect (PAE) is evident. The PAE is a persistent suppression of bacterial growth following the removal of an antimicrobial agent. Bactericidal action persists after serum concentrations fall below minimum inhibitory concentrations (MICs). This has ramifications for the design of clinical dosage regimens.

Spectrum of Activity

Aminoglycosides are effective against most gram-negative bacteria, including gram-negative bacteria of the Enterobacteriaceae and *Pseudomonas aeruginosa*. They are effective against staphylococci, although

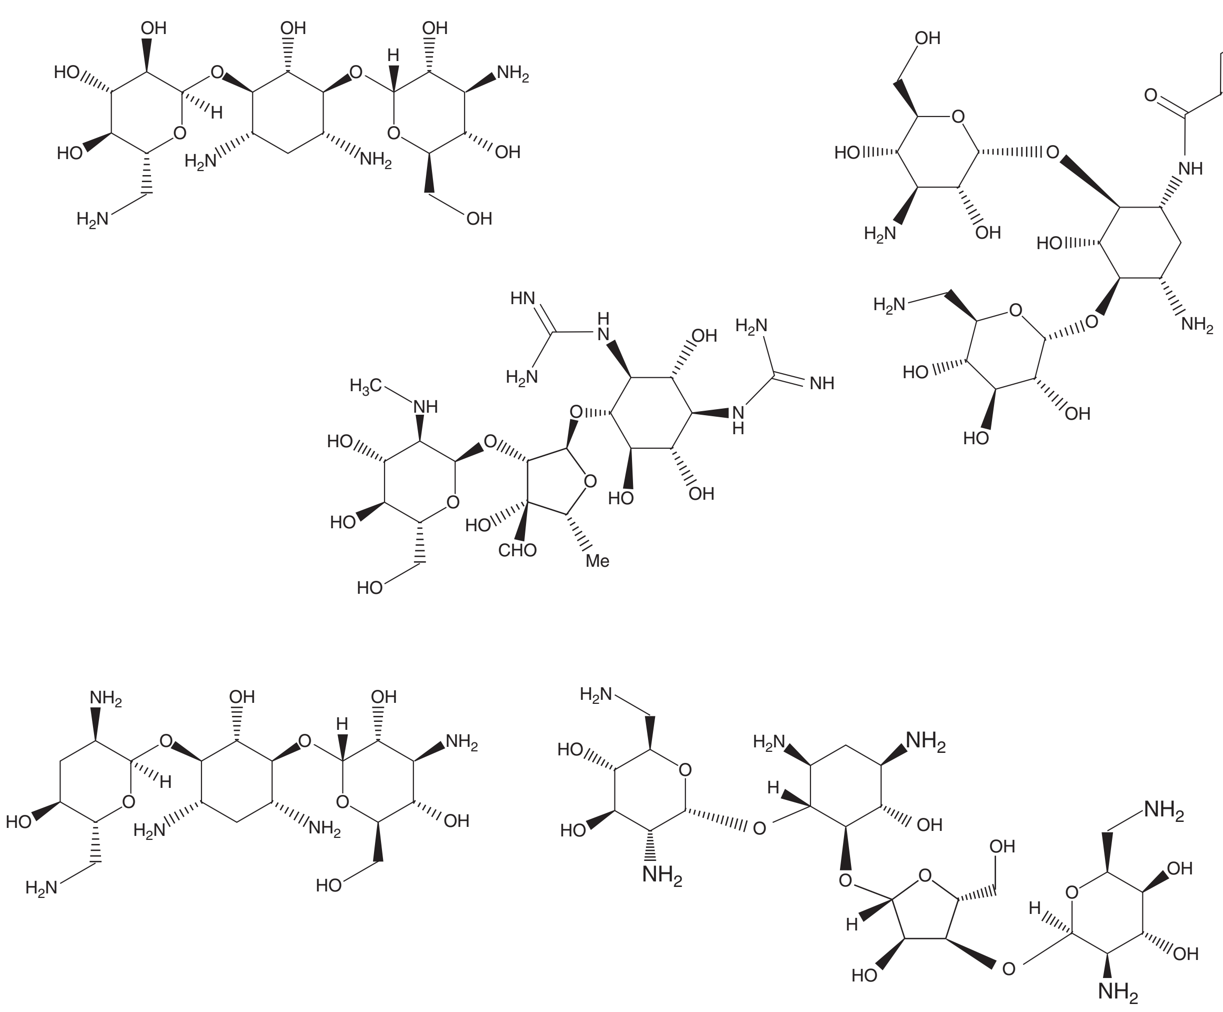

Figure 35.2 Structure of kanamycin, streptomycin, tobramycin, neomycin, and amikacin.

resistance can occur if used as monotherapy. Their action against streptococci and enterococci is limited unless they are combined with a β-lactam antibiotic. They have poor activity against *Pasteurella multocida*. Anaerobic bacteria are inherently resistant because drug transport into bacteria is oxygen dependent. Breakpoints for susceptibility testing have been established by the Clinical Laboratory Standards Institute (CLSI, 2015) and are shown in Table 35.1.

Comparison among drugs

Compared to other drugs in this group, amikacin usually has greater activity against gram-negative bacteria because it resists degradation by bacterial enzymes. This difference is observed with *E. coli* and particularly *Pseudomonas aeruginosa*. It is common for isolates obtained from dogs, cats, and horses to be resistant to gentamicin, yet still susceptible to amikacin. Gentamicin is approximately equal to tobramycin in activity, but tobramycin can be more active against some strains of *E. coli* and *Pseudomonas aeruginosa*. Kanamycin is least active compared to the others in this class, except for streptomycin.

Effect of tissue environment and other drugs on activity

pH effect: The action of aminoglycosides is pH dependent. The activity is less at low pH because high cation concentrations inhibit activity. The optimum pH for antibacterial activity is between 6 and 8. For example, gentamicin is 30 to 100-fold less active in an acidic (pH of 5.5 to 6.0) environment than at a pH of 7.4. Consequently, in some tissues and fluids (e.g., urine and abscesses) drug activity may be less because of lower pH.

Cellular debris: Aminoglycosides are bound to, and inactivated by, cellular debris and nucleic acid material that is released by decaying white blood cells. Therefore,

Table 35.1 Once-daily dosages for selected aminoglycosides

Species	Dose (in most cases the dose can be administered IV, IM, or SC)
Gentamicin	
Dog	9–14 mg/kg q 24 h
Cat	5–8 mg/kg q 24 h
Horse	Adult: 4–6.8 mg/kg q 24 h Foal (<2 weeks): 12–14 mg/kg q 24 h
Cattle	Adult: 5–6 mg/kg q24h Calf (<2 weeks): 12–15 mg/kg q 24 h
Sheep	Same as cattle
Amikacin	
Dog	15–30 mg/kg q 24 h
Cat	10–15 mg/kg q 24 h
Horse	Adult: 10 mg/kg q 24 h, IV, IM Foal (<weeks): 20–25 mg/kg q 24 h, IV

the activity in an abscess is poor. (One ml of purulent material can inactivate 700 μg of gentamicin.)

Oxygen tension: Low oxygen tension, such as that found in anaerobic tissue or decaying tissue, decreases the activity of aminoglycosides.

Cations: Because the uptake into bacteria is dependent on the drug's positive charge, divalent cations (e.g., Ca^{++}, Mg^{++}) can interfere with uptake of aminoglycosides into bacteria. Monovalent cations also may have some nonspecific inhibitory effect. The effects of cations on activity are discussed in Section Aminoglycoside Toxicity.

Other drugs: Aminoglycosides are inactivated if combined in vitro (for example in a vial or syringe) with other drugs, especially penicillins. This inactivation does not occur in vivo because concentrations in serum are not high enough to interact when two drugs are administered concurrently at the usual recommended doses. Aminoglycosides are synergistic with β-lactams against some bacteria in vitro, but this may not translate to improved clinical efficacy when the drugs are used simultaneously.

Resistance mechanisms

Anaerobic bacteria are intrinsically resistant because oxygen is necessary for aminoglycosides to enter bacteria. Resistance can occur by way of multiple effects. Some bacteria have an altered cell surface receptor, which is necessary to transport the drug into the bacteria. Bacteria can have a mutation in the target (ribosome) that resists binding, but this is uncommon.

A significant mechanism of resistance is degradation by bacterial enzymes. Several enzymes can be produced by bacteria that inactivate aminoglycosides. These enzymes can phosphorylate, adenylate, or acetylate groups on the molecule to render the drug inactive. The inactive drug can compete with the active drug for transport. Most drugs in this class are susceptible to many of the enzymes, but amikacin is susceptible to only one of the acetylase enzymes, which may account for amikacin's increased activity against some resistant bacterial strains in comparison to other aminoglycosides.

Pharmacokinetic–Pharmacodynamic Properties

The aminoglycosides are concentration-dependent bactericidal agents; therefore the higher the drug concentration, the greater the bactericidal effect. An optimal bactericidal effect occurs with peak drug concentration of 8–10 times the MIC, with little added benefit for concentrations above 10 times MIC. This target can be accomplished by administering a single dose once daily. This regimen is at least as effective, and perhaps less nephrotoxic, than lower doses administered more frequently (Freeman et al., 1997; Maglio et al., 2002; Drusano et al., 2007). Currently accepted dose regimens in small animals and horses employ this strategy. An additional benefit may be decreased resistance. According to Freeman et al. (1997), "Peak/MIC ratio of at least 10/1 may prevent the emergence of aminoglycoside-resistant pathogens". The single daily dose is usually calculated from the drug's volume of distribution. The peak may be achieved from IV, IM, or SC dosing. Total plasma concentration can be used because these drugs are essentially unbound (protein binding less than 10%).

Clinical Uses

The drugs used most often to any extent in veterinary medicine are amikacin, gentamicin, kanamycin, and neomycin (neomycin is used topically only). Netilmicin, sisomicin, and dibekacin are newer compounds but there are no reports of their use in veterinary medicine. Many streptomycin products have either been removed from the human market or are used only for certain infections (e.g., tuberculosis in people). Penicillin–dihydrostreptomycin combinations have been discontinued in the USA for use in animals.

Aminoglycosides are still considered to be important drugs of choice for treating serious aerobic gram-negative infections in veterinary medicine, although newer and less toxic antimicrobials (i.e., third-generation cephalosporins and fluoroquinolones) have replaced the use of aminoglycosides for some bacterial infections.

Neomycin is too toxic to be used systemically but is still used topically or oral for treating diarrhea. Kanamycin, was first introduced in the late 1950s, but many organisms are now resistant to this aminoglycoside and its use has subsequently declined. Gentamicin, introduced in the 1960s, has a broader spectrum and is associated with

Table 35.2 Susceptibility testing guidelines for aminoglycosides. Source: Data from CLSI. 		MIC interpretive category (µg/ml)			
Drug	**Species**	**S**	**I**	**R**	**Comments**
Gentamicin	Dogs	≤ 2	4	≥ 8	Once-daily dose of 10 mg/kg
	Horses	≤ 2	4	≥ 8	Once-daily dose of 6.6 mg/kg
Amikacin	Dogs	≤ 4	8	≥ 16	Once-daily dose of 15 mg/kg
	Horses adult	≤ 4	8	≥ 16	Once-daily dose of 10 mg/kg
	Foals	≤ 2	4	≥ 8	For foals less than 11 days of age, 20 mg/kg, q 24 h, IV
Spectinomycin	Bovine	≤ 32	64	≥ 128	Respiratory pathogens

S, susceptible; I, intermediate; R, resistant.

less resistance than kanamycin. Amikacin, a semisynthetic derivative of kanamycin, was introduced clinically in the 1970s, has the broadest spectrum of activity of all the aminoglycoside antibiotics used clinically to date, and is the preferred antibiotic in severe gram-negative infections that are resistant to gentamicin or tobramycin.

Table 35.2 lists the dosage regimens for some of the aminoglycosides. It is important to note that these doses can be modified proportionately to correct for age, clinical or subclinical disease processes, renal insufficiency, or any of the other factors that may predispose the patient to aminoglycoside toxicosis (see Section Aminoglycoside Toxicity). Alterations in the dose can be best determined by monitoring serum creatinine concentrations or optimally by monitoring aminoglycoside serum concentrations at predetermined time points after dosing.

Single Daily Dose Administration

Because of the PK-PD properties, discussed in Section Pharmacokinetic–Pharmacodynamic Properties, single daily dosing of aminoglycosides may be as efficacious as administering the same dose divided over 24 hours. The concept of single daily dosing of aminoglycosides has been utilized and generally accepted within the human medical community (Bass et al., 1998; Christensen et al., 1997; Freeman et al., 1997; Karachalios et al., 1998; Rodvold et al., 1997). The efficacy of single dose administration is attributed to the rapid bactericidal action and the PAE, discussed in Section Mechanism of Action. Once-daily aminoglycoside dosage regimens that produce high peak and low trough concentrations also have less propensity to induce renal toxicity than multiple-dose regimens, which produce lower peak but higher trough concentrations. The clinical doses listed in Table 35.2 are derived from studies in these species that show that once-daily administration can achieve the targeted PK-PD value (Albarellos et al., 2004; Godber et al., 1995; Tudor et al., 1999; Martin et al., 1998; Magdesian et al., 1998; Bauquier et al., 2015; Tudor et al., 1999).

Local Administration

Intraarticular administration of aminoglycosides achieves higher concentrations in joint fluid compared to systemic therapy. This mode of administration may not be practical in all cases and is used most often in horses compared to other animals. In studies performed in experimental horses with septic arthritis, intraarticular administration of gentamicin (150 mg/joint) produced a much higher concentration in synovial fluid than IV administration. Twenty-four hours later, horses that received intraarticular gentamicin also had fewer bacteria in the synovial fluid. Amikacin and other drugs also have been administered via this route.

Aminoglycosides can be implanted directly using antibiotic-impregnated polymethylmethacrylate (AIPMMA) in the infection site. This material is a type of bone cement that hardens at the site once mixed and prepared. Antibiotics impregnated in this matrix results in high local concentrations that are released for a long period of time – sometimes for as long as 80 days. This technique avoids high systemic levels of drugs, reduces drug costs, and the need for frequent systemic administration. Aminoglycosides (tobramycin, amikacin, and gentamicin) are often used for this technique (Streppa et al., 2001).

Regional perfusion of antibiotics involves intravenous or interosseous administration of antibiotic in the limb of an animal while a tourniquet is applied proximal to the site of drug administration. This technique was reviewed by Rubio-Martinez and Cruz (2006). It has been performed in horses, cattle, and large zoo animals (e.g., elephants). It produces high concentrations of antibiotic in the distal limb (joint fluid and bone) of an animal (Murphey et al., 1999). High bactericidal concentrations are achieved during the interval when the tourniquet is applied. Then, concentrations quickly dissipate after tourniquet release. The high concentrations enter adjacent tissue via perfusion and can penetrate ischemic tissue and exudate via gradient diffusion. This technique reduces the total amount of drug used and maintains high concentrations in bone and joint fluid distal to the tourniquet. The advantage of regional limb perfusion has been that it confines the drug to the lower limb, preventing systemic exposure, and avoids the need for high systemic doses (Anderson et al., 1995). Drugs used in this technique have usually been amikacin, gentamicin, or tobramycin. For example, gentamicin has been used to treat infections in horses using regional limb perfusion, particularly for lower limb and joint infections (Whitehair et al., 1992a, 1992b).

Susceptibility Testing

Clinical breakpoints have been established by the Clinical and Laboratory Standards Institute (CLSI) through an analysis of pharmacokinetics, PK-PD criteria, and MIC distributions. These breakpoints are listed in Table 35.1.

Regulatory Status

Although they are not banned by the US FDA, much of the use in food-producing animals is considered extralabel, except for a few oral products used to treat diarrhea. Under the animal medical drug use clarification act (AMDUCA) of 1994, extralabel use is not allowed if there are other approved animal products effective for the condition being treated. More information is available in Chapters 52 and 61 of this book. These drugs have very long withdrawal times for slaughter. As long as 18 months for withdrawal prior to slaughter in cattle is suggested by the food animal residue avoidance data bank (FARAD). The American Association of Bovine Practitioners (AABP) and Academy of Veterinary Consultants (AVC) have recommended that, until further scientific information becomes available, aminoglycosides should not be used in cattle.

Pharmacokinetics of Aminoglycosides

General

A comprehensive review of aminoglycoside pharmacokinetics has been reported by Brown and Riviere (1991) and is found in earlier editions of this book. The pharmacokinetics of the aminoglycosides is similar across species lines, but the variability within each animal population is large, indicating a significant amount of heterogeneity in aminoglycoside disposition in both diseased and normal animals (Sojka and Brown, 1986; Frazier et al., 1988). Although there is variability in aminoglycoside pharmacokinetic parameters, the therapeutic range for all of the aminoglycosides is relatively narrow, and the potential for toxicosis is greater than for most other classes of antimicrobials. Altered physiological or pathological states such as pregnancy (Lelievre-Pegorier et al., 1985), obesity (Sketris et al., 1981), subnormal body weight (Tointon et al., 1987), kidney disease (Frazier and Riviere, 1987; Martin et al., 1998; Martin-Jimenez and Riviere, 2001), dehydration (LeCompte et al., 1981; Brown et al., 1985a), immaturity (Sojka and Brown, 1986), sepsis (Mann et al., 1987), dietary protein (Grauer et al., 1994; Behrend et al., 1994), endotoxemia (Wilson et al., 1984; Jernigan et al., 1988c), and intraindividual variability (Mann et al., 1987), among many others, may alter the distribution, clearance, and half-life of aminoglycosides by as much as 1000-fold between individuals in a single study (Zaske et al., 1982).

Absorption

Aminoglycosides are not appreciably absorbed from the gastrointestinal tract because of their highly polar and cationic nature. However, if there is significant disruption of the intestinal mucosa from enteritis (Gemer et al., 1983; Miranda et al., 1984; Gookin et al., 1999), some absorption may occur. For example, neomycin administered orally to calves with enteritis could increase the risk of residues at slaughter. The aminoglycosides are not inactivated in the intestine and are eliminated in the feces unchanged after oral administration to normal animals. This lack of significant absorption through the gastrointestinal tract requires that all aminoglycosides be given by parenteral routes if therapeutic plasma concentrations are desired. Aminoglycoside absorption is practically complete after IM or SC injection. The peak serum concentrations after extravascular injection occur 14–120 minutes after the dose (Blaser et al., 1983; Ristuccia, 1984). Absorption is extremely rapid and complete if aminoglycosides are instilled into body cavities that contain serosal surfaces; administration by this route closely mimics parenteral administration (Jawetz, 1984; Sande and Mandell, 1985). Absorption from topical administration in open wounds also is possible and may increase the risk of nephrotoxicosis if high doses are used (Mealey and Boothe, 1994).

Distribution

The aminoglycoside antibiotics are highly hydrophilic and distribute rapidly in extracellular body fluids. Because of their polycationic nature, the penetration of aminoglycosides across membranous barriers by simple diffusion is limited; therefore, low concentrations of aminoglycosides are found in cerebrospinal fluid or in respiratory secretions (Riviere and Coppoc, 1981b; Strausbaugh and Brinker, 1983). Aerosol or intratracheal administration of aminoglycosides produces negligible serum concentrations in animals and this has been used for in-hospital treatment of bronchitis. Through this route, substantial bronchial and pulmonary concentrations can be achieved (Riviere et al., 1981b; Wilson et al., 1981). Delivery with devices that nebulize these agents for delivery to the airways has been employed in hospitalized patients with gentamicin, amikacin, and tobramycin.

Plasma protein binding is negligible for all drugs in this group. These drugs easily pass from the capillaries through fenestrations in capillaries to achieve concentrations in interstitial fluids that are equivalent to plasma drug concentrations. The volume of distribution is approximately equal to the volume of extracellular fluid (typically in the range of 20–25% for most adult animals).

Physiological changes can alter the distribution. Decreases in body water (dehydration) can decrease the volume of distribution and increase plasma drug concentrations. Increases in body water caused by pregnancy, third-compartment fluid accumulation (e.g., ascites), and young age (neonate) will increase the volume of distribution and lower plasma drug concentrations. In studies performed in calves, foals, and puppies, the high body water – particularly extracellular water – produces a high volume of distribution for aminoglycosides. Because the plasma concentration is proportional to the volume of distribution: the larger the volume of distribution, the higher the dose that is needed to attain a targeted peak plasma concentration (C_{max}). For example, the volume of distribution for gentamicin or amikacin in foals is more than double the value for adult horses. Subsequently the dose needed to maintain the same blood concentration should be increased, at least by twofold.

Metabolism and Excretion

Several studies in animals (Black et al., 1963; Chiu et al., 1976; Chung et al., 1980; Gyselynck et al., 1971; Schentag and Jusko, 1977; Silverman and Mahon, 1979) have clearly demonstrated that aminoglycosides are eliminated nonmetabolized from the body in all animal primarily by renal glomerular filtration. Some degree of proximal tubular reabsorption occurs and results in an intracellular sequestration or storage in the tubule cells without a significant transepithelial flux from the intraluminal to peritubular space. Net aminoglycoside secretion along more distal nephron segments may also occur. Proximal tubule luminal absorption of aminoglycoside appears quantitatively to be the primary mechanism of intracellular uptake; however, selective peritubular or basolateral reabsorption, evident in isolated tissue slice studies, does occur and may be of toxicological significance in specific situations. Reabsorption requires metabolic energy and occurs along the midconvoluted and straight portions of the proximal tubule (Barza et al., 1980; Bennett et al., 1982; Hsu et al., 1977; Kaloyanides and Pastoriza-Munoz, 1980; Kluwe and Hook, 1978a, 1978b; Kuhar et al., 1979; Pastoriza-Munoz et al., 1979; Senckjian et al., 1981; Silverblatt, 1982; Silverblatt and Kuehn, 1979; Silverman and Mahon, 1979; Tulkens and Trouet, 1978; Vandewalle et al., 1981; Williams et al., 1981a, 1981b; Zaske, 1980). Renal cortical uptake of the aminoglycosides is dose-dependent up to a threshold concentration; then, cortical accumulation increases at a progressively slower rate as the dose is increased. Cumulative uptake of aminoglycosides in tissues indicates that the kidney is the major site of drug sequestration.

A typical plasma vs time profile for IV administration of an aminoglycoside antibiotic to animals shows three phases. The α (distribution) phase occurs within the first hour after IV dosing, the β phase (elimination) occurs between 1 and 24 hours after IV dosing (and probably the most useful in determining dose adjustments in clinical situations), and the γ phase occurs 24 hours after dosing and is the most important part of the elimination curve of aminoglycosides when considering drug residues in food-producing animals. Values for the beta- and gamma-phases are shown in Table 35.4 for gentamicin. The primary difference in pharmacokinetics among species is related to the glomerular filtration rate (GFR). The GFR is lower for larger animals because of allometric scaling; therefore, larger animals tend to have slower clearance and the half-lives are longer (Riviere, 1985; Riviere et al., 1997). Reptiles have lower GFR and lower renal clearance of aminoglycosides. This produces longer half-lives in reptile species.

The prolonged terminal elimination phase of aminoglycosides has major implication for veterinary therapeutics in food-producing animals. As discussed in Section Metabolism and Excretion, aminoglycosides accumulate in the renal cortex for prolonged periods of time, resulting in violative tissue residues even after short periods of administration. In some cases, aminoglycosides such as gentamicin may be detected for a year after parenteral administration! A withdrawal time of 18 months for cattle treated with gentamicin has been recommended by FARAD (see Chapter 61), but it is best to simply avoid use in these species altogether. Piglets may be treated up to 3 days of age with oral products, but even in this case the withdrawal time is 40 days.

Pharmacokinetics in Nonmammals

Veterinarians involved in nonmammal practice should be aware of variations in elimination in some animals. In birds the elimination half-life is usually 2–3 hours and dosing intervals are similar to what has been used in mammals. For amphibians and reptiles, however, elimination rates are much slower. Half-lives range from 38 to 72 hours in alligators and dose intervals of 72 to 96 hours have been used. In snakes half-lives can be as long as 80–121 hours. In turtles and tortoises, the half-life of

Table 35.3 Risk factors that predispose to aminoglycoside toxicosis

Age

Concurrent administration of loop diuretics
Methoxyflurane anesthesia
Cephalosporin antibiotics
Nephrotoxic drugs

aminoglycosides has been in the range of 20–70 hours, with dose intervals usually every 48 hours to every 96 hours. Kidney injury may be greater because of the slower elimination in reptiles. Therefore, use these drugs cautiously in animals with slow clearance.

Aminoglycoside Toxicity

Aminoglycoside toxicity in domestic and laboratory animals was reviewed extensively by Riviere (1985). The possible risk factors that may predispose a patient to aminoglycoside toxicity are shown in Table 35.3.

Aminoglycosides can induce ototoxicity and nephrotoxicity because both organs have higher-than-normal concentrations of phospholipid (in particular, phosphatidylinositol) (Sastrasinh et al., 1982a, 1982b) in their cellular matrixes. Cationic aminoglycosides are chemically attracted to anionic membrane phospholipids. The tissues into which gentamicin preferentially accumulates (renal cortex and cochlear tissue) have disproportionately high amounts of phosphatidylinositol in their membranes compared with other tissues of the body (Hauser and Eichberg, 1973). Basolateral membranes of the renal proximal tubular epithelium also have a higher capacity for binding aminoglycosides than brush-border membranes because of their higher phosphatidylinositol content (Josepovitz et al., 1985).

Ototoxicity studies in a variety of species have shown injury from aminoglycosides that may affect both auditory and vestibular function due to destruction of the sensory hair cells in the cochlea and vestibular labyrinth. The mechanism of ototoxicity was described in a review (Lanvers-Kaminsky et al., 2017). Initially the outer hair cells of the cochlea are affected, which impars hearing at high frequencies. With continued exposure the inner hair cells are injured, which causes additional hearing impairment and deafness. Injury may be caused by oxidative stress and inhibition of mitochondrial protein synthesis. Aminoglycosides enter the inner ear by active transport mechanisms. Once in the ear, they are cleared slowly with half-lives of 10–13 days after a single dose, but up to 30 days after multiple doses. Ototoxicity may be irreversible in some cases (Johnson and Hardin, 1992). Of pertinence to veterinary medicine, dogs tend to present with auditory toxicity, and cats tend to present with vestibular toxicity, although both usually occur after nephrotoxicity has ensued.

The interaction between the cationic aminoglycosides and the kidney anionic phospholipids appears to be electrostatic and proportional to the cationic charge of the drug. This interaction is saturable and is competitively inhibited by divalent cations (magnesium and calcium), spermine, poly-L-lysine, and other aminoglycosides. For example, diets high in calcium, or calcium supplementation may decrease the risk of aminoglycoside nephrotoxicity (Schumacher et al., 1991; Brashier et al., 1998). After binding, the aminoglycoside is internalized into the cell by pinocytosis (Bennett et al., 1982; Elliott et al., 1982; Feldman et al., 1981; Humes et al., 1982; Lipsky et al., 1980; Lipsky and Lietman, 1982; Pastoriza-Munoz et al., 1979; Schacht, 1978), where concentrations of the aminoglycoside can reach as high as 50 times the concentrations achieved in serum or plasma. The uptake of aminoglycosides into lysosomes is competitive and is dependent in part upon the charge density of the aminoglycoside molecule, which is a function of the number of amino groups. For example, neomycin (valence + 4.37 at pH 7.40) accumulates in the renal cortex more than gentamicin (valence + 3.46 at pH 7.40) due to a higher cationic charge.

There are several mechanisms that may explain the mechanism by which aminoglycosides initially damage the proximal renal tubule cells (Swann et al., 1990; Schumacher et al., 1991; Beauchamp et al., 1992). Lysosomal dysfunction is a component of the early phase of renal injury (Carbon et al., 1978; Feldman et al., 1982; Hull et al., 1981; Kaloyanides and Pastoriza-Munoz, 1980; Laurent et al., 1982; Lipsky and Lietman, 1982; Mazze, 1981; Meisner, 1981; Morin et al., 1980, 1981; Tulkens and Trouet, 1978). This view is consistent with the idea that lysosomes are the primary locus of aminoglycoside sequestration in proximal tubule cells. Lysosomes are also the first organelle to demonstrate morphological changes (myeloid body or cytosegresome formation) after exposure to the drugs (Riviere et al., 1981a). Decreased lysosomal function may also result in a decreased ability to degrade endogenous intracellular proteins and exogenous low-molecular-weight proteins reabsorbed from the tubular filtrate, events that would perturb nephron function (Cojocel et al., 1983; Cojocel and Hook, 1983). The increase in lysosomal permeability could result in proximal tubule cell dysfunction, although this event is probably a late change in aminoglycoside-induced toxic nephropathy occurring after cell necrosis has been initiated by another factor (Humes et al., 1982). The appearance of lysosomal enzymes (for example, urinary γ-glutamyl transferase, GGT) in the urine of aminoglycoside-induced toxic nephropathy patients is secondary to proximal tubule cell necrosis, apical plasma membrane damage, or lysosome exocytosis.

Mitochondria are a second possible target of aminoglycosides because, both in vitro and in vivo, aminoglycosides decrease mitochondrial respiration, thereby impairing the tubule cell's bioenergetic profile (Appel and Neu, 1977; Cuppage et al., 1977; Kaloyanides and Pastoriza-Munoz, 1980; Kluwe and Hook, 1978a; Sastrasinh et al., 1982b; Simmons et al., 1980; Weinberg et al., 1980, 1990; Weinberg and Humes, 1980). This could selectively produce tubule dysfunction, which would initially be detectable biochemically but not morphologically. The mechanism of this toxicity may be secondary to a direct aminoglycoside interaction with mitochondrial membrane phospholipids, to a competitive interaction with the divalent cations magnesium or calcium, or to an alteration in the intracellular milieu that would indirectly affect mitochondrial function. The magnitude of aminoglycoside effects on mitochondrial respiration is associated with the net positive charge of the specific drug.

The third possible site of initial intracellular aminoglycoside is an interaction with the proximal tubule cell plasma membrane's phospholipids and enzymes (Feldman et al., 1981; Humes et al., 1982; Knauss et al., 1983; Lullmann and Vollmer, 1982; Sastrasinh et al., 1982a, 1982b; Schacht, 1979; Silverman and Mahon, 1979; Williams et al., 1981a, 1981b). Binding of aminoglycosides to membrane polyphosphoinositides could perturb the regulation of membrane permeability, thereby promoting cellular dysfunction. The enzyme interactions at the basolateral membrane could result in significant cellular dysfunction by altering intracellular electrolyte balance or osmolality.

An additional site of aminoglycoside interaction with the nephron is at the level of the glomerulus, where gentamicin has been demonstrated to reduce the glomerular ultrafiltration coefficient and to reduce the number and size of glomerular endothelial fenestrae (Avasthi et al., 1981; Huang et al., 1979; Luft and Evan, 1980a, 1980b; Luft et al., 1978). These effects may be mediated by a charge interaction between the cationic aminoglycosides and the anionic endothelial cell surfaces or could be a feedback response to a primary tubular injury (known as tubuloglomerular feedback).

The relative contributions of the lysosomal, mitochondrial, and membrane tubular mechanisms and glomerular injury to clinical aminoglycoside-induced toxic nephropathy is not known. It is possible that cellular dysfunction is a result of a combination of the above processes.

Dogs

Aminoglycoside-induced kidney injury in dogs follows a progression that consists of an initial subclinical (subazotemic) phase marked by a urinary concentrating defect followed by a clinical (azotemic) phase. It also serves as the basis for simple noninvasive clinical monitoring (for example, monitoring urine specific gravity and proteinuria) for toxicosis since urinary changes preceded the more irreversible systemic changes. If identified early, aminoglycoside-induced kidney injury can recover.

Urine GGT (γ-glutamyl transferase):creatinine and NAG (*N*-acetyl-β-D-glucosaminidase):creatinine ratios and 24-hour urinary excretions of NAG and GGT have been used as markers of aminoglycoside-induced kidney injury. Elevated GGT:creatinine ratio precedes clinically significant elevations in serum creatinine, urine specific gravity, and urine protein:creatinine ratios.

Risk factors in dogs (Brown et al., 1985a) were identified that contributed to nephrotoxicosis in 10 dogs. Risk factors included dehydration, fever, old age, and preexisting renal disease. In addition, low protein and electrolyte abnormalities were documented in these dogs. Other risk factors are shown in Table 35.3.

Ototoxicity in dogs, manifested as either vestibulotoxic and/or ototoxic effects, can occur after systemic aminoglycoside therapy, but toxicity after topical use of aminoglycosides is apparently rare (Strain et al., 1995). Although it is sometimes recommended among dermatologists to avoid topical gentamicin in animals with a ruptured tympanum (ear drum) this apparently is not a risk. In a study designed to detect ototoxicity in dogs treated with topically administered gentamicin using brain stem auditory evoked potential (BAEP), dogs underwent a unilateral myringotomy, followed by instillation of 7 drops of the 3 mg/ml buffered aqueous solution of gentamicin instilled into one ear twice a day for 3 weeks. There was no evidence in any treated dogs of drug-induced detectable changes in cochlear or vestibular function.

Cats

Cats have a relatively more concentrated urine and retain the ability to produce concentrated urine even when the GFR is significantly reduced (Ross and Finco, 1981), making urine monitoring less successful than in dogs. Consistent with the studies cited in dogs, studies in cats have shown that high doses, prolonged administration, or both, can produce kidney injury, with histological changes and increases in serum urea nitrogen and creatinine (Welles et al., 1973; Waitz et al., 1971).

Nephrotoxicosis associated with the topical use of gentamicin has been reported in cats (Mealey and Boothe, 1994). A cat was administered 10 ml of an undiluted gentamicin injectable solution (50 mg/ml) to lavage an open wound twice. The cat eventually progressed to an azotemic state and was euthanized. Histologically, the kidneys showed severe acute proximal tubular necrosis compatible with aminoglycoside toxicosis. Elevated serum levels of gentamicin were noted as late as 96 hours after administration. Although a number of factors may have contributed to the death of this cat, the topical administration of such large quantities of gentamicin was most likely the major determinant.

Horses

As in other animals, aminoglycoside-induced kidney and otic injury has been documented in horses (Nostrandt et al., 1991). Clinically, aminoglycoside-induced toxic nephropathy is more common in young animals, with toxicity rarely reported in adults (Riviere et al., 1982; Tobin, 1979). As in other animals the injury is marked by elevations in serum creatinine and serum urea nitrogen (Tobin, 1979; Riviere, 1982). The shift in dosing regimens from multiple times per day, to once per day has apparently decreased the risk of aminoglycoside-induced kidney injury in recent years and is now the accepted protocol used clinically (Tudor et al., 1999; Geor and Papich, 2003; Godber et al., 1995).

Examples of Drugs

Gentamicin

Gentamicin is available in solutions of 5, 50, and 100 mg/ml (Garasol, Gentocin, and generic), as well as oral solution for pigs (4.35 or 5 mg/ml) and powder for oral solution (66.7 or 333.3 mg per gram of powder) Gentamicin has been the most commonly administered drug in this class used in veterinary medicine. The common clinical approach is to rely on gentamicin for IV, IM, or SC administration when routine use of an aminoglycoside is indicated. In some instances (for example, to broaden the spectrum) it may be administered with a β-lactam antibiotic (e.g., penicillin, ampicillin, or a cephalosporin). Examples of gentamicin dosages are listed in Table 35.2. Representative pharmacokinetic data for gentamicin in animals are shown in Table 35.4.

Intramuscular injection is a reliable route of delivery as the absorption (bioavailability, F) of gentamicin from IM sites is high, usually approaching 90% or higher in most species (Jernigan et al., 1988e; Haddad et al., 1985b, 1986; Wilson et al., 1989; Pedersoli et al., 1989, 1990; Bird et al., 1983) and bioavailability from SC sites is similar to IM bioavailability (Gilman et al., 1987; Jernigan et al., 1988e; Wilson et al., 1989). Subcutaneous administration is acceptable but the maximum concentration after SC administration is usually lower and occurs later after injection than that observed after an equivalent IM dose (Jernigan et al., 1988a; Wilson et al., 1989), which is most likely due to less blood flow to the SC injection sites than to the IM injection sites, resulting in a slower rate of absorption but not altering the extent of absorption. Systemic availability from intrauterine (IU) administration is 30% in normal cows, with maximum plasma concentrations of 3.70 μg/ml and 17.5 μg/ml being observed 30 minutes after IU doses of 2 and 4 mg/kg, respectively (al-Guedawy et al., 1983).

Effect of Age on Disposition of Gentamicin

As discussed in the disposition section earlier, neonatal animals have a larger proportion of their body weight as extracellular fluid; therefore, gentamicin volume of distribution (Vd) is larger in immature animals than in adults. The difference is usually at least twofold higher in young animals compared to adults (Riviere and Coppoc, 1981a; Sojka and Brown, 1986; Riviere et al., 1983; Cummings et al., 1990; Clarke et al., 1992).

Because systemic clearance of gentamicin relies on kidney function, this also is affected by age and is typically lower in neonates (Sojka and Brown, 1986; Sweeney et al., 1992; Martin et al., 1998; Frazier et al., 1988; Riond et al., 1986). Clearance is correlated with the plasma creatinine concentration (Sweeney et al., 1992; Martin et al., 1998).

Effect of Body Condition and Disease on Gentamicin Disposition

Because gentamicin and other drugs from this class are water soluble, dehydration reduces the apparent volume of distribution (Hunter et al., 1991; LeCompte et al., 1981). Likewise, gentamicin does not distribute to fat and obese animals will have a lower apparent volume of distribution than lean animals (Wright et al., 1991). Dose adjustments should be considered when administering gentamicin to obese animals, extremely lean animals, and animals with fluid accumulations (e.g., ascites).

In endotoxemic animals, there was decreased plasma gentamicin concentrations in dogs and cats by approximately 20–30% (Pennington et al., 1975; Jernigan et al., 1988c). However, differences between healthy and febrile goats were not significant (Ahmad et al., 1994). In a population pharmacokinetic model across species, the covariate of fever seemed to influence gentamicin volume of distribution (Martin-Jimenez and Riviere, 2001). Other

conditions that have been shown to alter gentamicin disposition include endocrinopathies, pregnancy, and other concurrent drug administrations.

Amikacin

Amikacin is approved for animals as a 50 mg/ml injectable solution (Amikin, Amiglyde) as well as an intrauterine infusion (250 mg/ml intrauterine solution) for horses. Tables 35.5, 35.6, and 35.7 list some selected pharmacokinetic parameters for amikacin in various species of animals. It is common to initially rely on gentamicin for routine aminoglycoside treatment, but when resistance is observed or suspected, amikacin should be considered because resistance is uncommon for amikacin. Amikacin is particularly important for treating infections caused by *E. coli* and *Klebsiella pneumoniae* that have acquired multidrug resistance from extended spectrum β-lactamase (ESBL). Amikacin is often one of the few agents, other than a carbapenem, that is active against these bacteria.

Amikacin shows in vitro activity against *Staphylococcus* spp., although it is not a common agent for treatment of staphylococcal infections. Many guidelines recommend addition of a β-lactam antibiotic for treating infections caused by *Staphylococcus* spp. Amikacin is considered for treating methicillin-reisistant *Staphylococcus pseudintermedius* infections of the skin and soft tissue. However, there may be an association between amikacin resistance and methicillin resistance in these isolates (Gold et al., 2014).

Like gentamicin, amikacin is hydrophilic and is rapidly taken up by either IM or SC administration with bioavailability of approximately 90% or higher (Gronwall et al.,

Table 35.5 Pharmacokinetic data for amikacin in horses, foals, and dogs

		Half-life (hour)	Volume of Distribution (l/kg)	Clearance (ml/kg/min)	Mean residence time (hour)

1989; Bloomfield et al., 1997; Jernigan et al., 1988d; Cabana and Taggart, 1973; Ziv, 1977; Baggot et al., 1985; Carli et al., 1990).

Amikacin is also used in reptiles (snakes, turtles) and has a rapid absorption, but slow renal clearance. In these animals, clearance of amikacin (like many other drugs in cold-blooded animals) is temperature dependent.

Pharmacokinetics have been studied in adult horses and foals. Pharmacokinetic data from various studies are summarized in Table 35.5. As for gentamicin, the volume of distribution in neonatal foals is much higher than adults, necessitating higher clinical doses (by at least two times) compared to adults.

Kanamycin

Kanamycin is among the least active aminoglycosides in comparison to gentamicin and amikacin. Subsequently, the clinical use of kanamycin has fallen out of popularity in veterinary medicine in recent years. For example, against clinical isolates of *Pseudomonas aeruginosa* the highest rate of resistance was for kanamycin (90% resistant) compared to gentamicin (7%) and amikacin (3%) (Rubin et al., 2008).

Because kanamycin has chemical properties that are similar to other aminoglycosides (amikacin is synthesized from kanamycin), pharmacokinetic properties are

ND, not determined; NR, not reported.

also similar. Absorption from IM or SC injection is complete and rapid, volume of distribution resembles the volume of extracellular fluid, and excretion from the kidneys is close to the glomerular filtration rate for that species.

Apramycin

Apramycin, an aminoglycoside derived from *Streptomyces tenebrarius* (Ryden and Moore, 1977), is available for veterinary use, but it has limited use. The only formulations currently approved in the US of this drug are powder (Apralan) to be added to feed (Type A medicated feed article) at 150 grams per ton of feed, and the soluble powder to be added to water (100 mg per liter) to deliver 12.5 mg/kg for 12 days of treatment in medicated water. For each formulation, the indication is to treat porcine colibacillosis (pig scours) caused by *Escherichi coli*. More details on apramycin in selected species are presented in Table 35.8.

Tobramycin

Tobramycin is produced by *Streptomyces tenebrarius* and is structurally similar to kanamycin. Tobramycin is not extensively used in veterinary medicine, although it is used occasionally in dogs and cats because of its good activity against most *Pseudomonas aeruginosa* organisms. Typically, amikacin is used more often when it is necessary to treat resistant infections. However, occasionally amikacin has been unavailable because of manufacturing shortages and tobramycin has been used as a substitute.

Pharmacokinetic properties (absorption characteristics, volume of distribution, clearance, and half-life) are similar to other aminoglycosides. In cats, tobramycin systemic clearance was 2.21 ± 0.59 and 1.69 ± 0.36 ml/min/kg after doses of 5 mg/kg and 3 mg/kg IV, respectively, and a Vd(ss) of 0.19 ± 0.03 and 0.18 ± 0.03 l/kg, respectively (Jernigan et al., 1988b). Bioavailability after IM and SC tobramycin administration in cats was rapid and complete (Jernigan et al., 1988d). Urine tobramycin concentrations following 2.2 mg/kg three times a day were 66 ± 39 μg/ml when urine was obtained as a 6-hour collection in dogs (Ling et al., 1981). In horses (Newman et al., 2013), after a dose of 4 mg/kg it had a volume of distribution of 0.18 l/kg, and elimination half-life of 4.6 hours, with a clearance of 1.2 ml/kg/min. It was over 80% absorbed from IM injection.

After IV administration to camels (Hadi et al., 1994), tobramycin (1.3 mg/kg) elimination half-life was 189 minutes. The apparent Vd (area method) was 245 ml/kg and Vd(ss) was 228 ml/kg. Clearance was measured at 0.9 ml/min/kg. After a 1.0 mg/kg IM dose of tobramycin, bioavailability was almost 91%, with an elimination half-life of 201 minutes.

Neomycin

Most neomycin is used topically or administered orally (e.g., Biosol used for enteritis caused by *Escherichia coli*) to achieve a local effect in the intestine. Approved formulations are powder for addition to feed at 715 grams per kg of feed (Neomix), or neomycin oral solution (200 mg/ml) to be added to drinking water, both the oral solution and feed additive are designed to deliver 22 mg/kg up to 14 days. The oral solution also may be administered directly to individual animals.

Pharmacokinetic information about neomycin's use in human and veterinary medicine is limited because systemic use is practically nonexistent, but some details are available in previous editions of this book.

Dihydrostreptomycin and Streptomycin

The clinical use of dihydrostreptomycin and streptomycin has declined substantially in veterinary medicine. An old formulation of penicillin–dihydrostreptomycin (Pen-Strep) is off the market in North America. There is still a formulation containing dihydrostreptomycin sulfate (500 mg/ml) registered for treatment of *Leptospira*

Table 35.8 Selected pharmacokinetic parameters of apramycin

Species	Volume of distribution (l/kg)	Clearance (l/kg/h)	Half-life (hour)	Reference
Sheep	0.167	0.078	90.96	Lashev et al., 1992
Cow (lactating)	1.263	12.164[a]	2.10	Ziv et al., 1995
Ewe (lactating)	1.446	14.142[a]	1.85	Ziv et al., 1995

Japanese quail	0.133[b]	0.186	0.50	Lashev and Mihailov, 1994
Pigeons	0.077	0.210	15.24	Lashev et al., 1992

[a] Value in ml/kg/min.

[b] V_α is area, not steady state.

in dogs, horses, pigs, and ruminants. Although dihydrostreptomycin has been used in the treatment of cows infected with *Leptospira interrogans* serovar *hardjo* subtype *hardjobovis* (Gerritsen et al., 1994), this use is not common and the product is not marketed.

There is an oral formulation of streptomycin (250 mg/ml) still registered for oral treatment of bacterial enteritis in pigs, cattle, and poultry. It has been administered directly or added to drinking water. Because the use of these products is uncommon, previous editions of this book should be consulted for more detailed information on their use.

After IM doses of 5.5 mg/kg dihydrostreptomycin, maximum concentrations ranged from 5.1 to 17.0 μg/ml, with peak concentrations occurring earlier and more variable from the commercial preparation containing procaine penicillin G, dihydrostreptomycin, dexamethasone, and chlorpheniramine than from the commercial product containing only dihydrostreptomycin and procaine penicillin G (Rollins et al., 1972). Half-lives range from 2.35 to 4.50 hours. Because streptomycin and dihydrostreptomycin are chemically very similar, their dispositions also may be nearly identical.

Paromomycin

Paromomycin is a wide-spectrum aminoglycoside antibiotic produced by *Streptomyces rimosus* var. *paromomycinus* and, unlike others in this class, has both gram-positive and gram-negative activity. Paromomycin is poorly absorbed from the gastrointestinal tract, which is clearly an advantage if used to treat certain bacterial or protozoal gastrointestinal infections. The pharmacokinetics of paromomycin in the dog has been described by Belloli et al. (1996); see Table 35.9.

Table 35.9 Pharmacokinetic parameters of paromomycin in the dog. Source: Belloli et al., 1996.

Parameter	IV	IM	SC
Half-life (hour)	91.03	114.22	120.86

VD_{ss} (l/kg)	0.33	ND	ND
Clearance (l/min/kg)	0.0037	ND	ND
C_{max} (μg/ml)	ND	32.1	36.3
F	ND	>0.99	>0.99
MRT (min)	98.7	204.8	203.8
K_{el} (min^{-1})	0.0186	0.0061	0.0057

ND, not determined.

Giardia, Leishmania, Entamoeba histolytica, and *Balantidium coli* are susceptible to paromomycin (Barr et al., 1994; Belloli et al., 1996). Paromomycin has been used to treat cryptosporidiosis in a cat (Barr et al., 1994) and leishmaniasis (*Leishmania infantum*) in dogs (Poli et al., 1997). However, a retrospective case study in cats treated with high-dose oral paromomycin (165 mg/kg) suggested that 4 of 31 individuals developed acute nephrotoxicity, deafness, and/or possible cataract formation (Gookin et al., 1999), implying that enough oral absorption occurred for this large and highly charged aminoglycoside to exert an adverse effect. Therefore, use of this drug at these high doses should be approached with caution until further data are available.

Chloramphenicol and Derivatives, Macrolides, Lincosamides, and Miscellaneous Antimicrobials

Mark G. Papich

Drugs listed in this chapter do not warrant a separate chapter and are included together, as they comprise narrow uses in veterinary medicine. They have some features in common – for example they inhibit protein synthesis in bacteria (with macrolides, lincosamides, and chloramphenicol acting at a similar site), and have some similar pharmacokinetic features.

Some of these drugs are not as common or available as in previous years. Some older drugs have given way to newer derivatives and their discussion has been greatly abbreviated in this edition of the book. Older editions may be consulted for more detailed and historical information.

Chloramphenicol

Chemical Features

Chloramphenicol chemically is D-(-)-threo-1-*p*-nitrolphenyl-2-dichloroacetamido 1,3-propanediol (Figure 36.1), has a pK_a of 5.5, and was first isolated from the soil organism *Streptomyces venezuelae* in 1947. The chloramphenicol used today is manufactured synthetically. Chloramphenicol is slightly soluble in water and freely soluble in propylene glycol and organic solvents. Chloramphenicol is a broad-spectrum antibiotic, inhibiting gram-positive and gram-negative organisms, aerobic and anaerobic bacteria, and many intracellular organisms. Chloramphenicol has three functional groups that largely determine its biological activity: the *p*-nitrophenol group, the dichloroacetyl group, and the alcoholic group at the third carbon of the propanediol chain (Yunis, 1988). Replacement of the *p*-NO_2 group by a methylsulfonyl (HC_3-SO_2) moiety produces thiamphenicol and a substantial change in biological activity, while modification of the propanediol group by the addition of a fluorine atom produces florfenicol. Both of these are discussed in more detail in Sections Thiamphenicol and Florfenicol. Loss of the dichloroacetyl group altogether results in loss of biological activity (Yunis, 1988; Hird and Knifton, 1986).

After the discovery of chloramphenicol in 1947 it was in popular use decades ago, but has been gradually replaced by safer alternatives. The small animal formulation is approved by the FDA (Chloromycetin) but is not actively marketed. The use of chloramphenicol diminished in the 1970s and 80s because other active and safer drugs became available. Today, chloramphenicol has experienced a bit of a resurgence in companion animal medicine. Multidrug resistant bacteria, particularly methicillin-resistant *Staphylococcus* spp., are usually susceptible to chloramphenicol and this is one of the most common drugs selected for use by small animal veterinarians (Papich, 2012; Bryan et al., 2012; Frank and Loeffler, 2012). Antibiotic-resistant *Enterococcus* spp. are also often susceptible. Chloramphenicol has the disadvantage of a narrow margin of safety in dogs and cats, and necessity of frequent administration in dogs to maintain adequate concentrations (three or four times daily oral administration). These disadvantages still exist, but the activity of chloramphenicol against bacteria (e.g., staphylococci) that are resistant to other oral drugs has created increased use of chloramphenicol in recent years.

Drug Formulations

Many formulations have been removed from the commercial market because chloramphenicol no longer is in wide use for humans. Chloramphenicol has FDA approval for use in dogs, and is available in 100, 250, and 500 mg tablets (Chloromycetin). The oral suspension of chloramphenicol palmitate is rarely available. Chloramphenicol is not soluble and injectable formulations include esters such as succinate and palmitate, glycinate, or undecylenate. There also has been a propylene glycol solution. None of the injectable formulations are used today. Although chloramphenicol is poorly soluble (<5 mg/ml), the poor solubility does not interfere with oral absorption. Chloramphenicol is absorbed orally

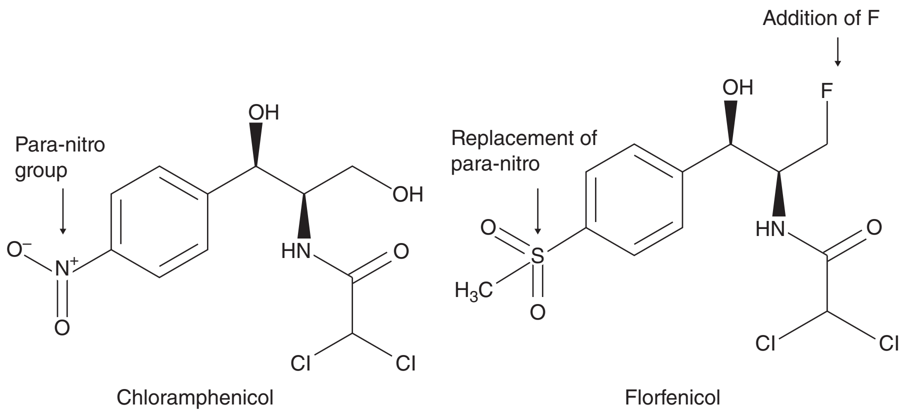

Figure 36.1 The chemical structure of chloramphenicol and modifications to form florfenicol.

with or without food (except some formulations in cats). Tablets and capsules have similar oral absorption in dogs. Topical formulations of chloramphenicol have been used for otic and ophthalmic use, but the otic formulations have been replaced by newer forms containing florfenicol.

Mechanism of Action

Chloramphenicol inhibits protein synthesis. Its biological activity is due to interference with peptidyltransferase activity at the 50S ribosomal subunit, which is near the site of action of macrolide antibiotics and for which there can be competition (Yunis, 1988). Because of the interaction with peptidyltransferase, binding with the amino acid substrate cannot occur, and peptide bond formation is inhibited. Chloramphenicol affects mammalian protein synthesis to some degree, especially mitochondrial protein synthesis. Mammalian mitochondrial ribosomes have a strong resemblance to bacterial ribosomes (both are 70S), with the mitochondria of the bone marrow especially susceptible. Prolonged administration to animals has been associated with a dose-related bone marrow suppression, especially in cats (Watson, 1980).

The action of chloramphenicol (and florfenicol) is regarded as bacteriostatic, rather than bactericidal (Maaland et al., 2015). There are isolated examples in which bactericidal effects have been observed, but chloramphenicol and similar drugs in this class usually behave as bacteriostatic agents and the drug concentration in animals should be maintained above the MIC for as long as possible during the dose interval.

Spectrum of Activity

Chloramphenicol has a broad spectrum of activity. It is active against *Staphylococcus pseudintermedius*, *S. aureus,* streptococci, and some gram-negative bacteria, such as *Pasteurella multocida*, *Mannheimia haemolytica*, and *Histophilus somni. Escherichia coli, Proteus* spp., and *Salmonella* spp. may be susceptible, but resistance can occur with many gram-negative bacteria, especially the Enterobacteraceae. One reason for the increased use of chloramphenicol, especially in dogs, is that it has retained activity against *Staphylococcus pseudintermedius,* including methicillin-resistant strains (Perreten et al., 2010). However, resistance by staphylococci may occur from repeated administration. Anaerobic bacteria, *Mycoplasma* spp., and many Rickettsiae also are susceptible. The Clinical Laboratory Standards Institute (CLSI, 2015) approved break point for susceptibility is ≤4 μg/ml for streptococci and ≤8 μg/ml for other organisms (Watts et al., 1999).

Bacterial Resistance

Four mechanisms of resistance to chloramphenicol have been described (Yunis, 1988; Schwarz et al., 2004). The most important is plasmid mediated due to the presence of the chloramphenicol acetyltransferase enzyme, which catalyzes a reaction that causes enzymatic inactivation by acetylation of the drug. This can occur through different types of chloramphenicol acetyltransferases (Schwarz et al., 2004). The acetyltransferases that cause resistance to chloramphenicol are less likely to affect florfenicol, making florfenicol more active against some pathogens (discussed in Section Florfenicol). Other mechanisms of resistance include efflux systems, inactivation by phosphotransferases, decreased bacterial cell wall permeability, altered binding capabilities at the 50S ribosomal subunit, and inactivation by nitroreductases.

Pharmacokinetics

Absorption and Distribution

The pharmacokinetic parameters of chloramphenicol have been studied in several animal species and are summarized in Tables 36.1 and 36.2. Chloramphenicol in animals is well absorbed via both oral and parenteral routes, with a few notable species exceptions. Plasma half-lives vary, ranging from 0.9 hours in ponies to 5.1 hours in the

cat (Davis et al., 1972). Fasted cats showed differences in absorption between the chloramphenicol tablets and the chloramphenicol palmitate suspension (Watson 1992). The liquid formulation showed a lower systemic drug availability, indicating that hydrolysis of the palmitate form is necessary and that there is a higher risk of drug failure when the palmitate suspension is used to treat sick cats that are also not eating. In ruminants, microflora present in the ruminant forestomach tend to metabolize chloramphenicol faster than it can be absorbed, making chloramphenicol administered orally of little use in ruminant animals. This point is rather moot since administration of chloramphenicol to food animals in the United States is currently illegal (discussed in more detail in Chapter 55). In most animals, 30–46% of chloramphenicol is bound to plasma proteins, leaving much of the drug in the free and active form. Chloramphenicol is widely distributed to many tissues of the body due to its nonionized state and high lipophilicity, enabling it to cross lipid bilayers quite easily. The volume of distribution (Vd) is typically greater than 1.0 l/kg and has been measured at 1–2.5 l/kg (Tables 36.1 and 36.2). Chloramphenicol reaches sufficient concentrations in most tissues of the body, including the eye, central nervous system (CNS), heart, lung, prostate, saliva, liver, and spleen, among others (Ambrose, 1984; Hird and Knifton, 1986). Chloramphenicol concentrations in cerebrospinal fluid (CSF) are approximately 50% of corresponding plasma concentrations. Chloramphenicol can also cross the placental barrier in pregnant animals and can diffuse into the milk of nursing animals.

Metabolism and Excretion

Chloramphenicol is metabolized by the liver after absorption into the systemic circulation. One of the largest drawbacks to chloramphenicol administration is the rapid metabolic clearance, producing short half-lives in many species and necessity for frequent administration. As shown in Table 36.1 for dogs, the short half-life translates to a need to be administered three times daily. In horses, because of rapid elimination rates, tissue fluid concentrations persisted for only 3 hours after IV administration of chloramphenicol sodium succinate (Brown et al., 1984). Phase II glucuronidation is the principal pathway for the hepatic biotransformation of chloramphenicol, with the principal metabolite being chloramphenicol glucuronide. A few hydrolysis products have also been identified. Cats excrete chloramphenicol more slowly than other animals, perhaps owing to the cat's deficiency in some glucuronidase enzymes. One report notes that 25% of the total dose of chloramphenicol is excreted in the urine in the active form in cats compared to 6% in dogs (Hird and Knifton, 1986). Most of the absorbed chloramphenicol (approximately 80%) is excreted into the urine as inactive metabolites via tubular secretion.

The effect of age on clearance of chloramphenicol is inconsistent. Calves showed differences compared to older cattle, but this is probably irrelevant because it should not be used in food animals (Burrows et al., 1984). Brumbaugh et al. (1983) found that in neonatal horses, elimination and Vd did not differ from adults. Bioavailability in foals was 83%, with an oral half-life of 2.54 hours.

Adverse Effects and Precautions

Bone marrow suppression has been the most important adverse effect associated with chloramphenicol administration to people. Bone marrow injury from chloramphenicol takes two forms (Yunis, 1988). The first type

NA, data not available; PG, propylene glycol.

is the most common and involves a dose-related suppression of the bone marrow precursor erythroid series. This toxicosis is reversible. The evidence suggests that this bone marrow suppression is the result of suppression of mitochondrial protein synthesis in bone marrow cells. In bone marrow cells there is vacuolation of the myeloid and erythroid series precursor cells, and inhibition of erythroid and granulocytic colony forming units (IARC, 1976, 1990). In both the dog and the cat, dose-related bone marrow suppression is possible. However, signs of toxicity reverse when chloramphenicol therapy is discontinued.

The second type of bone marrow toxicity, aplastic anemia, has been described in people but not in animals. In people, it is rare and independent of dose and treatment duration. This toxicity results in bone marrow aplasia, chiefly characterized by a profound and persistent pancytopenia. Aplastic anemia occurs in approximately 1 : 10,000 to 1 : 45,000 humans who receive chloramphenicol. It appears that the para-nitro group of the chloramphenicol molecule is responsible for this more serious form of bone marrow toxicity (Figure 36.1). The para-nitro group undergoes nitroreduction, leading to the production of nitrosochloramphenicol and other toxic intermediates, which trigger the stem cell damage in humans (IARC, 1976, 1990; Yunis, 1988). Modification of the molecule to eliminate the para-nitro group to produce either thiamfenicol or florfenicol reduces the risk of chloramphenicol-associated aplastic anemia (Figure 36.1).

Chloramphenicol-induced aplastic anemia in humans is important from a food-animal residue standpoint. If chloramphenicol is used to treat infections in food animals, it is possible that low concentrations of chloramphenicol in milk, meat, and other edible tissues from the animals will be consumed by people and cause aplastic anemia in susceptible individuals. Chloramphenicol residues have been known to persist for prolonged periods in food animals (Korsrud et al., 1987). Even though the amount consumed may be small, reaction that may occur in people are not dependent on dose. Thus, there is a public health risk for individuals consuming these products. For this and other reasons, the use of chloramphenicol in food-producing animals has been banned in the United States. The hazards of using chloramphenicol in food animals have also been reviewed by others (Settepani, 1984; Lacey, 1984).

Other adverse effects caused by chloramphenicol in animals have been observed since the drug is used more in recent years to treat drug-resistant bacteria. Young animals and cats are sensitive to intoxication due to impaired glucuronidation pathways. Cats given 60 and 120 mg/kg/day PO every 8 hours for 21 and 14 days (respectively) showed clinical signs of depression, dehydration, reduced fluid intake, weight loss, emesis, and diarrhea. Bone marrow hypoplasia was also documented in addition to pancytopenia (Watson, 1980). Other investigators (Penny et al., 1967, 1970) administered to cats 50 mg/kg/day IM, with the cats showing marked depression and inappetence by day 7 of administration, severe bone marrow changes by day 14, and becoming extremely ill by day 21.

Gastrointestinal (GI) disturbances are among the most common in dogs (Short et al., 2014; Bryan et al., 2012). Dogs may exhibit events such as vomiting, diarrhea, anorexia, drooling, gagging or any combination of these clinical signs. They tend to resolve when the medication is discontinued. These effects may be related to GI injury as oral administration resulted in intestinal mucosal damage and diarrhea in calves and reduced glucose absorption (Rollin et al., 1986). Another issue that has emerged now that chloramphenicol is used more often is peripheral neuropathy. In one report, this adverse effect was almost as common as the gastrointestinal problems (Short et al., 2014). Signs that may be observed are ataxia, rear limb weakness, trouble standing, and/or jumping, or trembling on the back legs. This is believed to be caused by peripheral neuropathy, but the cellular mechanism is unknown. One microscopic study in three dogs (Kuroda et al., 1974) identified degenerative changes in peripheral nerves. Larger-breed dogs may be at higher risk for the neuropathy based on anecdotal accounts. Most dogs recover when the medication is discontinued.

Drug Interactions

Chloramphenicol is an inhibitor of the cytochrome P450 (CYP) drug-metabolizing enzymes. Enzyme specificity has not been fully characterized, but there is evidence that one of the enzymes inhibited is canine CYP2B11 (Martinez et al., 2013). Among the drugs substrates that may be affected by inhibition from chloramphenicol are anticonvulsants (e.g., phenobarbital), propofol, benzodiazepines, and other anesthetics. For example, chloramphenicol significantly affected metabolism of methadone in dogs (KuKanich and KuKanich, 2015).

Clinical Use

The FDA-approved dose for dogs is 55.5 mg/kg oral, every 6 hours. This dose is likely to increase the risk of adverse effects and the most common clinical dose, based on pharmacokinetic studies and evidence of efficacy is 50 mg/kg every 8 hours oral. Chloramphenicol has been used for treatment of a wide range of susceptible microbial infections, including those caused by salmonellae, intracellular and extracellular bacteria, rickettsiae, and mycoplasmata; infections of the eyes and CNS; and infections due to anaerobic organisms (IARC, 1976, 1990). One of the reasons for its popularity has been the high lipophilicity. Chloramphenicol readily penetrates cells, making it active against intracellular bacteria. It can penetrate tissues that otherwise are difficult to treat, such as the CNS, which is further discussed below. Chloramphenicol was shown in one study to be equally effective for treatment of Rocky Mountain spotted fever in dogs as enrofloxacin and tetracyclines (Breitschwerdt et al., 1990). Chloramphenicol has been used to treat infections caused by *Staphylococcus* spp., streptococci, *Brucella* spp., *Pasteurella* spp., *E. coli, Proteus* spp., *Salmonella* spp., *Bacillus anthracis, Arcanobacterium pyogenes, Erysipelothrix rhusiopathiae,* and *Klebsiella pneumoniae.* It is consistently active against anaerobic bacteria.

Chloramphenicol has been suggested for treatment of infections of the CNS (encephalitis, meningitis) because it is able to cross the inflamed or uninflamed blood–brain barrier and attain therapeutic concentrations in the CSF and the brain. Despite the rationale for this use, some experts have suggested that since chloramphenicol is merely bacteriostatic against gram-negative pathogens, and there is a lack of phagocytes or immunoglobulins in CSF, chloramphenicol is not well suited to treat serious infections of the CNS (Rahal and Simberkoff, 1979).

Chloramphenicol attains high concentrations in the eye when given systemically or after topical application on the cornea and is useful in treating susceptible bacterial conjunctivitis, panophthalmitis, endophthalmitis, and bacterial diseases of the cornea (Conner and Gupta, 1973). Topical formulations are not as readily available owing to the risk of aplastic anemia (discussed in Section Adverse Effects and Precautions), which can be caused by topical exposure.

Chloramphenicol has been used to treat bacterial infections of the respiratory tract because it may have better penetration across the blood–bronchus barrier into respiratory secretions and respiratory lining fluid than more polar or less lipophilic antibiotics. Respiratory infections in horses, dogs, cats, and exotic animals are among the uses of oral chloramphenicol.

Chloramphenicol is among the few drugs that can be administered orally to horses with safety. It achieves moderate systemic absorption of 21–40% (Gronwall et al., 1986) and has no serious adverse effects on the equine digestive system. For treatment in horses, tablets or capsules are mixed with vehicles such as molasses or corn syrup to facilitate oral administration. Chloramphenicol has been administered to horses for respiratory infections, pleuritis, CNS infections, and joint infections. Because there are other active drugs available, it is most often considered as an option when bacteria are resistant to other antibiotics. The recommended doses are based on specific pharmacokinetic studies in adults and foals (Gronwall et al., 1986; Brumbaugh et al., 1983).

Chloramphenicol has been administered to exotic animals, especially reptiles and amphibians, to treat a variety of infections (Clark et al., 1985); although florfenicol (see Section Florfenicol) has taken over some of these uses. Chloramphenicol administration in 15 species of birds was examined, and the investigators concluded that after IM injections of 50 mg/kg, chloramphenicol would produce adequate concentrations to treat susceptible bacteria for 8–12 hours, except in pigeons, macaws, and conures because effective concentrations could not be achieved in these birds (Clark et al., 1982). However, oral absorption was poor, and this route of administration was discouraged for all birds.

Chloramphenicol Derivatives

The ban on the use chloramphenicol in food-producing animals in the mid-1980s left a gap in the veterinarian's armamentarium of effective antimicrobial drugs. Because the idiosyncratic aplastic anemia is associated with the presence of the para-nitro group on the chloramphenicol molecule, attempts were made to modify the chloramphenicol structure to simultaneously retain chloramphenicol's broad spectrum of antimicrobial activity and eliminate the induction of aplastic anemia in people. Compounds synthesized in attempts to accomplish this goal are thiamphenicol and florfenicol. Thiamfenicol is not approved in the United States and will be discussed here only briefly. However, florfenicol has been approved for use in pigs, cattle, and fish (in some countries) and has been effective for treatment of various infections, especially bovine respiratory disease in cattle and swine respiratory disease in pigs intended for human consumption.

Thiamphenicol

Thiamphenicol is a semisynthetic structural analog of chloramphenicol. It is not available in North America; therefore, all of the experience has been learned from research studies or use in other countries. The major structural difference between chloramphenicol and thiamphenicol is that the para-nitrophenol group has been replaced by the methyl sulfonyl moiety (Figure 36.1). The mechanism of action and spectrum are similar to that of chloramphenicol. However, its structural differences result in different pharmacokinetic properties and decreased potency. Thiamphenicol is more water soluble and less lipid soluble and therefore diffuses more slowly through lipid membranes. It is not metabolized to a significant extent in the liver (Ferrari et al., 1974) and most of the dose is excreted in the urine as the unchanged active compound (Yunis, 1988; Lavy et al., 1991a; Gamez et al., 1992). Resistance to thiamphenicol is also similar to that of chloramphenicol, with bacterial acetylation of the thiamphenicol molecule, but at a rate approximately 50% less than that of chloramphenicol.

Few pharmacokinetic studies have been performed on food-producing animals, but thiamphenicol pharmacokinetics has been studied in veal calves (Gamez et al., 1992) and lactating goats (Lavy et al., 1991a). Both studies found thiamphenicol to have a large volume of distribution and rapidly eliminated in the urine. In dogs, thiamfenicol had a half-life of 1.7 hours and a volume of distribution of 0.66 l/kg (Castells et al., 1998). In dogs the injection of thiamfenicol was well absorbed, with availability of 97%, but the terminal half-life was longer (5.6 hours), suggesting slow release from the injection site.

Thiamphenicol is considered to be less toxic than chloramphenicol, yet a reversible bone marrow suppression has been reported in humans. However, millions of people have been treated with thiamphenicol in countries in which it is approved, with no reports linking its use to aplastic anemia (Adams et al., 1987). In a thiamphenicol toxicity study in rabbits (Kaltwasser et al., 1974), no changes attributed to thiamphenicol in erythrocyte, reticulocyte, or plasma iron parameters were noted after long-term treatments of up to 90 mg/kg/day.

Florfenicol

Florfenicol is structurally related to thiamphenicol; however, florfenicol contains fluorine at the 3′ carbon position (Figure 36.1). The fluorine molecule substitution at this position also reduces the number of sites available for bacterial acetylation reactions to occur, possibly making the antibiotic more resistant to bacterial inactivation. Florfenicol is as potent, or more potent, than either chloramphenicol or thiamphenicol against many organisms in vitro. The study by Maaland et al. (2015) using *Staphylococcus pseudintermedius* and *E. coli* isolates, showed that there were fewer nonwild-type isolates for florfenicol than chloramphenicol. There were no nonwild-type isolates of *Staph. pseudintermedius* for florfenicol. These results agree with previous studies that show that resistance mechanisms may be less likely for florfenicol compared to chloramphenicol (Schwarz et al., 2004).

The list of susceptible bacteria for florfenicol is the same as listed previously for chloramphenicol. However, as mentioned earlier, some bacteria resistant to chloramphenicol because of inactivation by acetylation may be susceptible to florfenicol. The CLSI (CLSI, 2015) quality control ranges of MIC for florfenicol are 2–8 μg/ml (Marshall et al., 1996). *Mannheimia haemolytica, Pasteurella multocida,* and *Histophilus somni* are several-fold more susceptible in vitro than bacteria of the Enterobacteriaceae, with MIC_{90} for *Pasteurella* and *Histophilus somni* in the range of 0.5–1.0 μg/ml. The CLSI breakpoints are ≤2 μg/ml (susceptible) 4 μg/ml (intermediate), and ≥8 μg/ml (resistant) for isolates of bovine and swine respiratory disease (CLSI, 2015). By comparison, the susceptible breakpoint for chloramphenicol is ≤8 μg/ml for organisms other than streptococci, and ≤4 μg/ml for *Streptococcus* spp. Florfenicol breakpoints for other animals and other bacteria have not been determined.

The advantage of florfenicol for administration to food animals is that it lacks the para-nitro group (Figure 36.1) that could contribute to the induction of aplastic anemia associated with chloramphenicol use in humans. Therefore, if residues were to occur in animals treated with florfenicol, no dangerous public health risk would ensue. However, it is possible that florfenicol can still produce a dose-related form of reversible bone marrow suppression with prolonged use or high doses. Such reactions have not been reported from routine use of florfenicol in animals, probably because it is rarely used for a long time. However, in one clinical account in a zoo animal, high doses induced bone marrow suppression (Tuttle et al., 2006).

Pharmacokinetics

The pharmacokinetics of florfenicol are summarized in Table 36.3.

Absorption: Studies in calves and other species listed in Table 36.3 show that absorption from all routes after either IM or SC injection is generally high. Oral absorption in horses and dogs was also high. After IM or SC injection, the absorption is slow and often prolonged in animals because of the vehicle in the solution. Therefore, the IM or SC injection produces a *flip-flop* effect, in which the terminal half-life is determined by the slow absorption. This can be seen in Table 36.3 in which the IM and SC half-life is generally much longer than the IV half-life. This effect prolongs the duration of effective concentrations.

Distribution: Like chloramphenicol, florfenicol has a wide distribution in most tissues of the body (Adams et al., 1987), with a volume of distribution approaching 1 l/kg (0.7–0.9 l/kg in most cattle studies) (Table 36.3). Protein binding is low in cattle with values of 13–19% reported (Bretzlaff et al., 1987; Lobell et al., 1994), but in other studies it was 5% at high concentrations and negligible at low concentrations in cattle plasma (Foster et al., 2016). Protein binding has not been reported for other animals. High concentrations are detected in the kidney,

Route of administration used is listed with dose. C_{max} is the maximal concentration after administration. ND, not determined. Empty cells indicate that the parameter is not relevant for the route administered.

urine, bile, and small intestine, but less penetration in the CSF, brain, and aqueous humor of the eye than that attained with chloramphenicol. Concentrations in brain and CSF are one-quarter and one half the corresponding concentrations in plasma, respectively. Although in one study the distribution into CSF was only 46% relative to plasma, these levels were high enough to produce concentrations in CSF of cattle to inhibit *Histophilus somni* for over 20 hours (De Craene et al., 1997). Florfenicol reached high concentrations in the synovial fluid of cattle following regional limb perfusion (Gilliam et al., 2008). Florfenicol also penetrated well into the milk of lactating goats after IV and IM administration; therefore, it could be used to treat microbial infections in the udder of lactating animals (Lavy et al., 1991b) if appropriate milk withdrawal times are available. The penetration into interstitial fluid was almost 98%, a reflection of the low protein binding. In the same study, the penetration into the pulmonary epithelial lining fluid of calves was over 200% and produced high concentrations for treating respiratory infections (Foster et al., 2016).

Metabolism and Elimination: The elimination half-life in various species and for different routes is shown in Table 36.3. Most of the dose administered to cattle is excreted as the parent drug (64%) in the urine, with the remaining excreted as urinary metabolites. Florfenicol amine is the metabolite that persists longest in tissues of cattle and is used as the marker residue for withdrawal determination.

Pharmacokinetic studies in other species: As seen in Table 36.3, there have been pharmacokinetic studies in small animals and some exotic and zoo animals. As in cattle, it has rapid clearance when injected IV, but more prolonged terminal half-life if administered by other routes.

Pharmacokinetic–pharmacodynamic properties: The Pharmacokinetic–pharmacodynamic (PK-PD) properties for florfenicol may be dependent on the organism studied. There is evidence for a bactericidal effect against some bacteria but not others (Maaland et al., 2015; Sidhu et al., 2014). Florfenicol may be bactericidal against isolates of *Staph. pseudintermedius but not E. coli* (Maaland et al., 2015). Against bovine isolates of *Mannheimia haemolytica* and Pasteurella multocida, florfenicol appears to have bactericidal activity. It is not established if the parameter for predicting efficacy is time above MIC (T>MIC) or area-under-the-curve (AUC) / MIC. It is likely that as for most other protein synthesis inhibiting agents with little or no postantibiotic effect, the AUC/MIC would be the best parameter to predict clinical efficacy. In a study in calves (Sidhu et al., 2014) a AUC/MIC ratio of approximately 18–27 was identified from modeling experiments.

Clinical Use

Florfenicol is available in three injectable solutions: 300 mg/ml solution for injection (Nuflor, or Nuflor gold), and a solution combined with flunixin meglumine (Resflor Gold, 300 mg/ml florfenicol plus 16.5 mg/ml flunixin). There is also a solution to be added to drinking water for swine (23 mg/ml, to be added as 400 mg per gallon) and a Type A medicated feed. For fish there is a 500 gram per kilogram premix for fish (Aqua-Flor).

Cattle and pigs: Several studies in cattle have been conducted to support the use of florfenicol for treating bovine respiratory disease caused by *Mannheimia haemolytica, Pasteurella multocida,* and *Histophilus somni*. Florfenicol penetrates well into the epithelial lining fluid of the airways of cattle (Foster et al., 2016), and has been effective for treating undifferentiated bovine respiratory disease (Hoar et al., 1998; Jim et al., 1999). There are two doses approved for cattle: 20 mg/kg SC or IM, given every 48 hours and injected in the neck, or a single dose for cattle at 40 mg/kg SC in the neck. Florfenicol is also approved for treatment of bovine interdigital phlegmon (foot rot, acute interdigital necrobacillosis, infectious pododermatitis) associated with *Fusobacterium necrophorum* and *Bacteroides melaninogenicus*.

Florfenicol has been effective in calves for treating experimentally induced infections and naturally occurring infectious bovine keratoconjunctivitis (Dueger et al., 1999; Angelos et al., 2000). In the naturally occurring case, florfenicol was administered one dose SC at 40 mg/kg or IM two doses 48 hours apart at 20 mg/kg. Concentrations persist in CSF for a long enough period after administration of 20 mg/kg in cattle that concentrations are above MIC of susceptible pathogens for at least 20 hours.

The swine dose is 15 mg/kg IM in the neck, every 48 hours. For pigs, florfenicol can also be added to the feed (182 g per ton of feed), or drinking water (400 mg per gallon) for 5 days for the control of swine respiratory disease associated with *Actinobacillus pleuropneumoniae, Pasteurella multocida, Streptococcus suis,* and *Bordetella bronchiseptica*.

Small animals: Although some pharmacokinetic studies have been conducted in small animals and exotic animals, there are no reports of efficacy. Pharmacokinetic studies in reptiles and dogs suggest that frequent dosing with high doses would be necessary to maintain plasma concentrations above the MIC for susceptible organisms throughout the dosing interval. By contrast, florfenicol solution in cats was absorbed well from both routes, with peak concentrations of 20 μg/ml and 27 μg/ml after IM and oral dose, respectively. Absorption was high from both routes (greater than 100% from IM and oral). The half-life was 5.6 hours and 7.8 hours for IM and oral dose, respectively. In cats, florfenicol produced inhibitory concentrations for 12 hours. These studies indicate that a dose of 22 mg/kg administered every 12 hours orally or parenterally would be adequate to produce sustained plasma concentrations for treatment of susceptible bacteria. Safety of these doses for small animals have not been established.

Topical forms: Two topical formulations were approved by the FDA in 2014 and 2015. The product Osurnia® contains 10 mg florfenicol, 10 mg terbinafine, and 1 mg betamethasone acetate per ml in a gel for topical administration. The product Claro™ contains florfenicol 15 mg/ml, terbinafine 13.3 mg/ml, and mometasone 2 mg/ml. The indication for each product is for the treatment of otitis externa in dogs associated with susceptible strains of bacteria (*Staphylococcus pseudintermedius*) and yeast (*Malassezia pachydermatis*).

Use in fish: Florfenicol has been administered orally for treatment of infections in captive fish and is approved in some countries for this use (Aqua-Flor®). Florfenicol is effective for treating bacterial infections in fish, such as trout and salmon (Fukui et al., 1987). Florfenicol premix is approved in some countries for treatment of furunculosis in salmon caused by *Aeromonas salmonicida*. Florfenicol has been administered orally for treatment of furunculosis caused by susceptible strains of *Aeromonas* *salmonicida* in captive fish and is approved in other countries. The premix (Aqua-Flor®) is approved for use in catfish and salmonids at a dose of 10 mg/kg for 10 days to treat susceptible fish pathogens.

The typical dose for fish is 10 mg/kg. At this dose, the half-life is 12–16 hours in most fish, with a peak (C_{max}) concentration of approximately 3–10 μg/ml (Pinault et al., 1997; Martinsen et al., 1993; Horsberg et al., 1994). Red pacu had a shorter half-life and lower C_{max} after 10 mg/kg IM (Lewbart et al., 2005). In sharks at a dose of 40 mg/kg IM, florfenicol produced effective levels for 120 hours (Zimmerman et al., 2006). Admnistration to sharks every 3–5 days will produce concentrations in a therapeutic range.

Other species: Pharmacokinetic studies in horses show that florfenicol has longer half-life than chloramphenicol, good distribution, and good absorption. However, in experimental horses there were consistent loose stools and elevated bilirubin (McKellar and Varma, 1996). Until additional studies are available to establish safe doses, florfenicol cannot be recommended for horses. Adverse effects were observed in alpaca at repeated doses of 40 mg/kg SC, but not in llamas administered a single dose of 20 mg/kg (Holmes et al., 2012; Pentecost et al., 2013). The authors recommended a dose in llamas of 20 mg/kg once daily, IM. After a single injection of 20 mg/kg (IM and IV) there were no adverse effects identified clinically or in blood tests in camels, sheep, or goats (Ali et al., 2003). However, the low concentrations achieved and the short half-life in the study by Ali et al., raises questions about whether or not it would be clinically effective at this dose.

In snakes (boas), the half-life was 28 hours from IM injection. It was estimated that 50 mg/kg once daily for boas is the best dose to produce therapeutic plasma concentrations, even though efficacy studies are not available. In sea turtles the clearance was rapid (60–100 ml/kg/h) and the half-life was short (Stamper et al., 2003). It was concluded that florfenicol was not a practical drug for treatment of infections in sea turtles.

Adverse Effects

Effect of florfenicol on bovine pregnancy, reproduction, and lactation have not been determined. Mild diarrhea and elevated bilirubin have been reported from administration to horses (McKellar and Varma, 1996). Reversible, dose-related bone marrow suppression is possible but not reported, except for a reaction reported in a zoo animal that was mentioned previously (Tuttle et al., 2006). In cattle, diarrhea and decreased feed consumption have been observed, which are transient. A local tissue reaction from IM or SC injection is possible. When toxic overdoses were administered to calves (200 mg/kg) there was marked anorexia, decrease in body weight, ketosis, and elevated liver enzymes. In dogs administered high doses for prolonged periods there was CNS vacuolation, hematopoietic toxicity, and renal tubule dilation. Adverse effects were detected in alpacas after a dose of 40 mg/kg SC that may be related to the prolonged concentrations at this dose (Table 36.3) (Holmes et al., 2012). These effects included significant hematological abnormalities and protein decrease. Caution should be used if administering to these animals for repeated doses.

Regulatory Information

The tolerance for florfenicol is 3.7 ppm for florfenicol amine (the marker residue) in liver and 0.3 ppm in muscle. Withdrawal time for use in salmon is 12 days. Withdrawal time for oral administration to pigs in feed is 13 days and for administration in water 16 days. After injection to cattle, the withdrawal time for slaughter is 28 days if injected at a dose of 20 mg/kg IM (36 days in Canada). If injected at a dose of 40 mg/kg SC, the withdrawal time for slaughter is 38 days. A formulation with different excipients (Nuflor Gold) has a withdrawal time of 44 days in cattle when injected at 40 mg/kg SC, once. More than 10 ml should not be injected at each site to avoid tissue reactions and injections should be administered in the neck (both SC and IM). Do not administer to dairy cows older than 20 months, to calves under 1 month of age, or to calves on an all-milk diet.

Macrolide Antibiotics

Source and Chemistry

The macrolide antibiotics are a group of structurally similar compounds, most of which are derived from various species of *Streptomyces* soil-borne bacteria. Chemically, all the drugs in this group are classified as macrocyclic lactones, with members containing 12–20 atoms of carbon in the lactone ring structure (Table 36.4). Attached to this lactone ring are various combinations of deoxy sugars held to the lactone ring

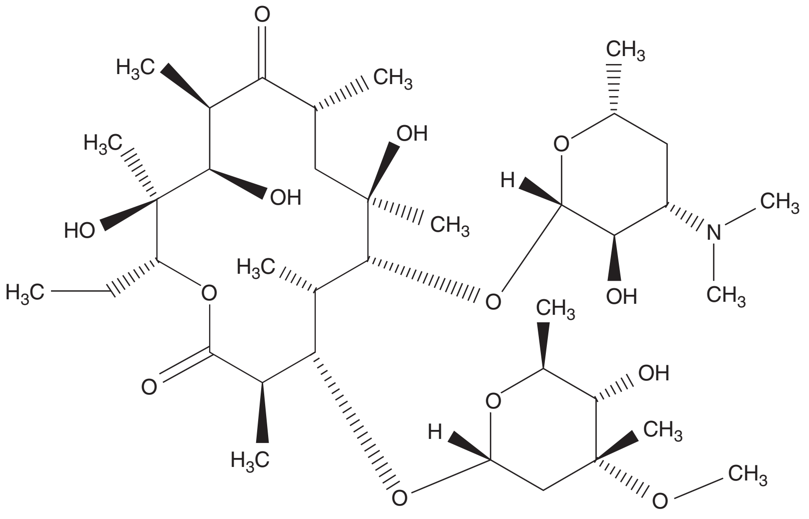
Table 36.4 Macrolides used in animals

Drug	Structure	Brand Name
Erythromycin	14 member ring	Gallimycin (and generic)
Tilmicosin	16 member ring	Micotil, Pulmotil
Azithromycin	15 member ring	Zithromax (human drug)
Gamithromycin	15 member ring	Zactran
Tylosin	16 member ring	Tylan
Tildipirosin	16 member ring	Zuprevo
Tulathromycin	15 member ring	Draxxin

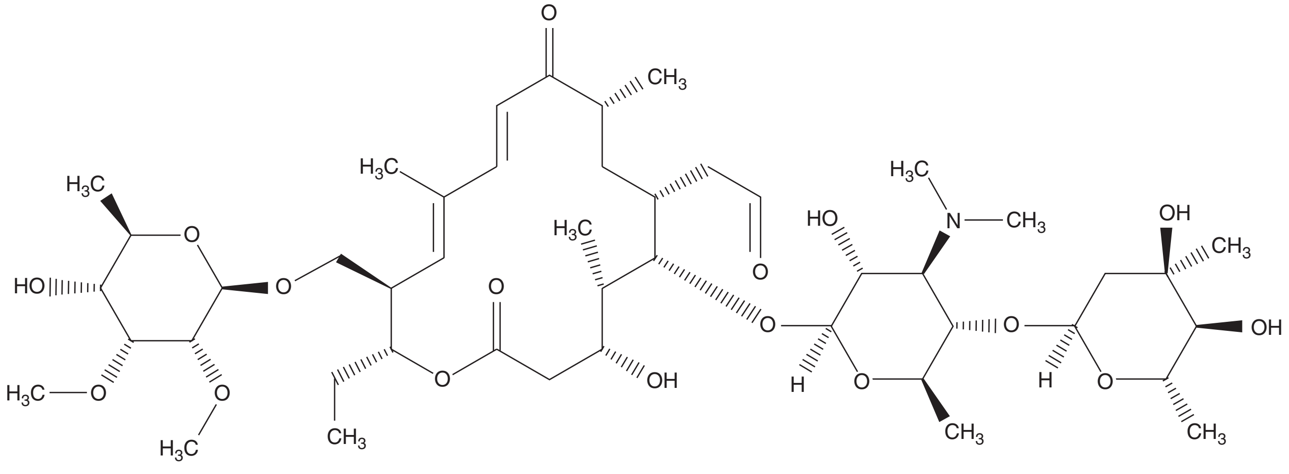
by glycosidic linkages. Since erythromycin's discovery in the early 1950s from the soil organism *Streptomyces erythreus,* numerous other macrolides have been isolated or synthesized from the parent molecule erythromycin, including tylosin, roxithromycin, erythromycylamine, tilmicosin, dirithromycin, azithromycin, tulathromycin, clarithromycin, spiramycin, and flurithromycin (Kirst and Sides, 1989). The most common agents used clinically in veterinary medicine are listed in Table 36.4.

Erythromycin and tylosin (Figure 36.2) are traditional macrolides. The newer drugs (Table 36.4 and Figure 36.3) were either developed for use in people (azithromycin) or specifically for use in cattle and/or pigs. These newer drugs differ from erythromycin in that they have a prolonged action and can be administered intermittently, or for just a single injection. Other macrolides such as oleandomycin and carbomycin have been used as feed additives for growth promotion in food animals and will not be discussed in detail here.

Macrolides are composed of a macrolactone ring of 12, 14, 15, or 16 carbon atoms, substituted with sugar moieties. Erythromycin, the prototype of this class, consists of a 14-atom polyhydroxylactone erythronolide ring and the two sugars clandinose and desosamine. Similarly, tylosin is composed of a 16-atom lactone ring (a tylonolide) to which three sugars – mycinose, mycaminose, and mycarose – are attached (Wilson, 1984; Kirst et al., 1982). Azithromycin is the first drug in the group of azalides, which are semisynthetic derivatives of erythromycin (Lode et al., 1996). Azithromycin has a 15-member ring structure. Tulathromycin, resembles azithromycin (Figure 36.3) and also has a 15-member ring structure. The structure of the newer agents includes basic nitrogen groups. All macrolides are weak bases, with pK_a ranges



Erithromycin



Tylosin

Figure 36.2 The chemical structures of erythromycin (top) and tylosin (bottom).

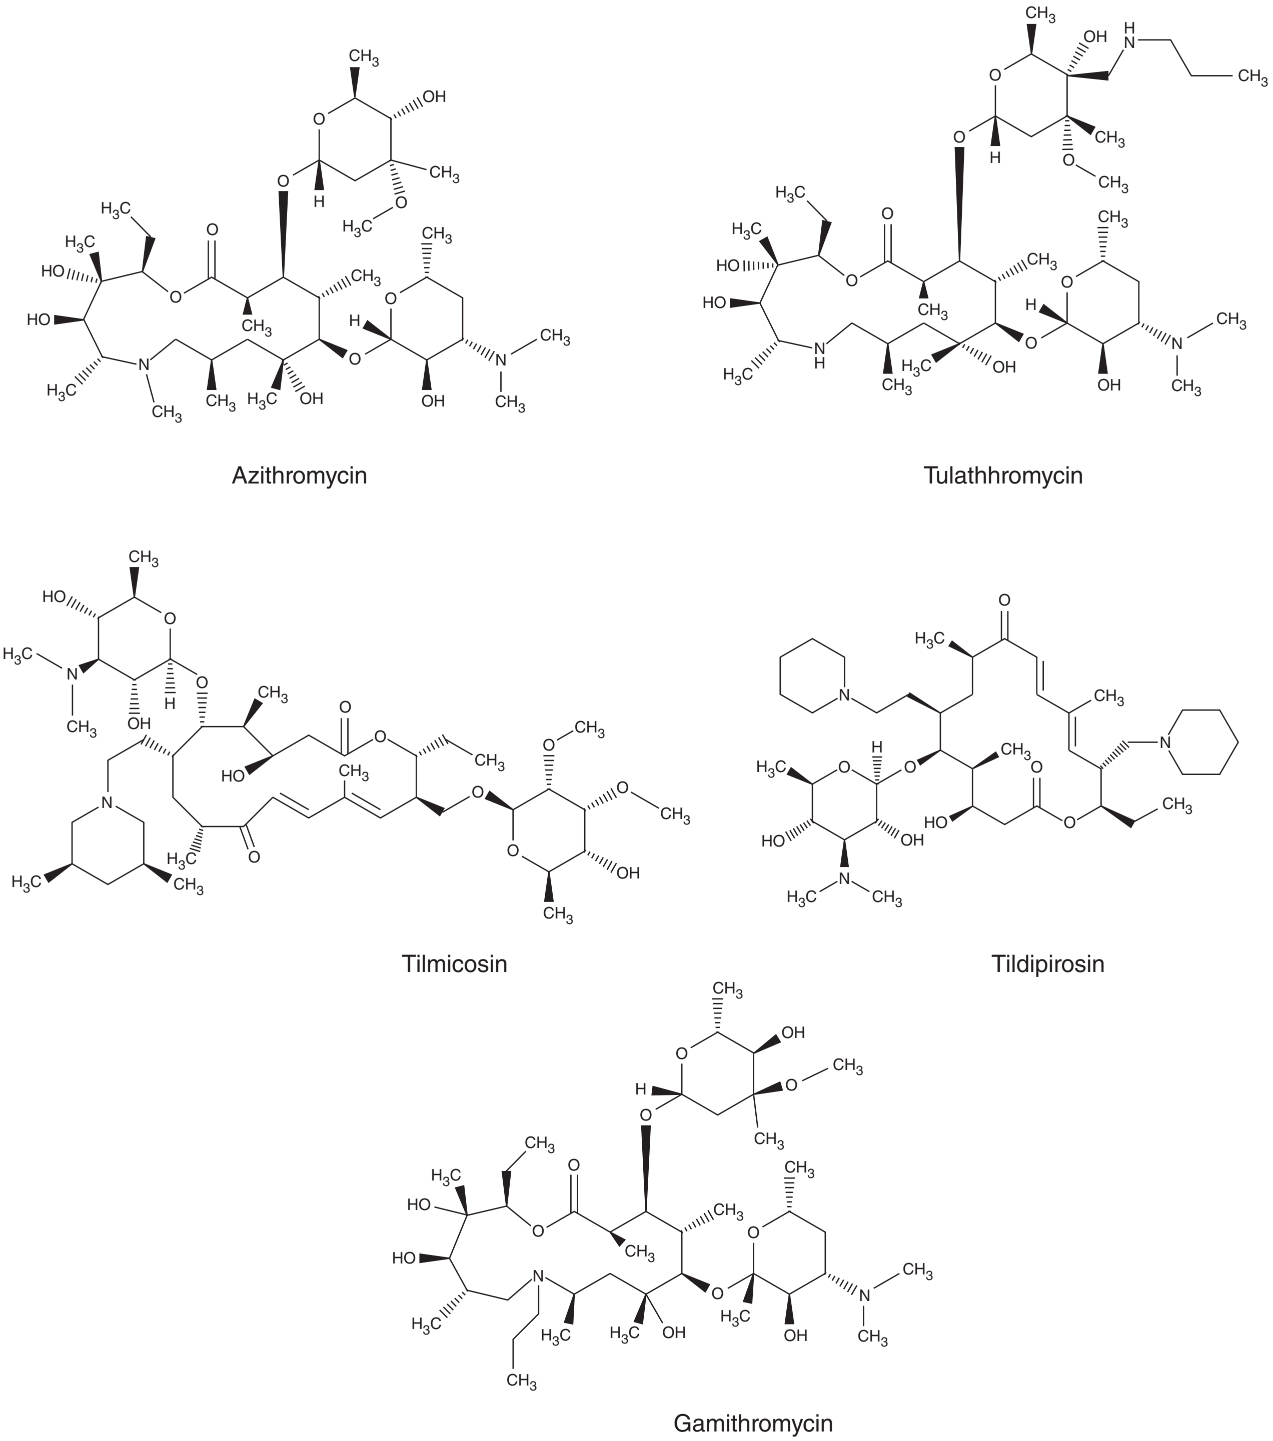


Figure 36.3 The chemical structures of new macrolide derivatives: azithromycin, tulathromycin, tildipirosin, tilmicosin, and gamithromycin. Azithromycin is a human drug and the others are approved for use in cattle and/or pigs.

from 6 to 9. They can have either two (di-basic) or three (tri-basic) nitrogen groups. For example, tulathromycin has three (tribasic) and has been referred to as a "trimilide". Tildipirosin also has three basic groups. The basic nitrogen groups on these newer agents (Figure 36.3) produces a positive charge in an acidic environment below their pKa. The positive charge increases the affinity for intracellular sites caused by ion trapping. It is this property that gives these agents such large intracellular distribution and a high volume of distribution.

Effect on Antibacterial Activity: The basic nature of the macrolides also influences the antibacterial activity. The in vitro antibacterial activity of macrolides varies according to the pH of the culture medium and the pH at the site of infection. Subsequently, antibacterial activity decreases in acid pH and increases in alkaline conditions. A change in pH of only 0.2 units has been known to change the MIC by a full Log-2 dilution step. These changes become important when CO_2 is used during culture incubation because it lowers the pH of the medium.

Mechanism of Action

The antibacterial action of macrolides is produced by an inhibition of protein synthesis by binding to the 50S ribosomal subunit at the 23S rRNA site of prokaryote organisms. The binding site on the ribosome is near, but not identical to, that of chloramphenicol, and antagonism of effect is possible if macrolides are administered with chloramphenicol. By binding to the 50S ribosomal site, macrolides cause dissociation of peptidyl-tRNA from the ribosomes during the elongation phase, which disrupts addition of new peptide bonds and thus prevents synthesis of new proteins. Although macrolides can bind to mitochondrial ribosomes, they are unable to cross the mitochondrial membrane (in contrast to chloramphenicol) and do not produce bone marrow suppression in mammals. Macrolides do not bind to mammalian ribosomes, making them a relatively safe group of drugs for veterinary use.

Although most authors have listed macrolides as bacteriostatic at therapeutic concentrations (Wilson, 1984), this effect may be both bacterial species, concentration, and drug dependent. For example, the agents developed for pigs and cattle (Table 36.4) can have bactericidal activity against bovine and swine respiratory pathogens, including *Mannheimia haemolytica, Pasteurella multocida*, *Histophilus somni,* and *Actinobacillus pleuropneumoniae*. As discussed above, the antimicrobial action of macrolides is enhanced by a high pH (Sabath et al., 1968), with the optimum antibacterial effect at a pH of 8. Therefore, in an acidic environment, such as in an abscess, necrotic tissue, or urine, the antibacterial activity is suppressed.

Resistance Mechanisms

Resistance to macrolides is usually plasmid mediated, but modification of ribosomes may occur through chromosomal mutation. Resistance can occur from: (i) decreased entry into bacteria (most common with the gram-negative organisms), and also mediated by *mef*-efflux genes, (ii) synthesis of bacterial enzymes that hydrolyze the drug, and (iii) modification of target (the ribosome in this instance) by RNA methylation or RNA sequence changes through mutation. The ribosomal attenuation (most common mechanism) involves methylation of the 50S drug receptor site. This resistance, coded by *erm* genes (e.g., *erm*A, *erm*B, *erm*C) may also lead to cross-resistance with other antibiotics that preferentially bind to these sites, such as other macrolides and lincosamides (Wilson, 1984). Resistance to erythromycin in animals in several microorganisms has been discussed in more detail elsewhere (Maguire et al., 1989; Dutta and Devriese, 1981, 1982a, 1982b; Leclercq and Courvalin, 1991; Devriese and Dutta, 1984). In small animals with staphylococcal infections, resistance was more likely if antibiotics had previously been prescribed, especially in cases of recurrent pyoderma (Lloyd et al., 1996; Medleau et al., 1986; Noble and Kent, 1992). Seven to 22% of small animal isolates of *Staphylococcus* spp. can exhibit resistance (depending on region and use), and in some countries this has remained relatively stable at around 22–24%.

Spectrum of Activity

Erythromycin is mainly effective against gram-positive organisms such as streptococci, staphylococci, including staphylococci that may be resistant to β-lactams because of β-lactamase synthesis or modification of the penicillin-binding protein target. Other organisms that show in vitro susceptibility to macrolides include *Mycoplasma, Arcanobacterium, Erysipelothrix, Bordetella,* and *Bartonella*. Although the spectrum favors the gram-positive group, a few gram-negative bacteria are susceptible, especially *Pasteurella* spp. Activity against anaerobic bacteria is only moderate. Most other gram-negative bacteria, such as those of the Enterobacteriaceae or *Pseudomonas* spp., are resistant. Azithromycin is an exception among the macrolides and can exhibit more activity against gram-negative bacteria. In addition to better activity against Enterobacteriaceae, it also has activity against other enteric pathogens, such as *Campylobacter* spp. (Gordillo et al., 1993).

The activity of newer derivatives (Table 36.4 and Figure 36.3) is similar to that of erythromycin, but these agents have better activity against respiratory pathogens, including *Pasteurella, Mannheimia haemolytica,* and *Histophilus somni,* which corresponds to their use for treating respiratory tract infections in pigs and cattle. These macrolides also have activity against *Mycoplasma* spp. The activity of macrolides against *Rhodococus equi* is important for treating lung infections caused by this organism in horses, particularly foals (Jacks et al., 2003). The MIC values for 32 antimicrobials against *Rhodococcus equi* were compared by Riesenberg et al. (2014). In decreasing order of activity, the MIC_{90} values for clarithromycin, erythromycin, azithromycin, tilmicosin, tylosin, tulathromycin were 0.06, 0.5, 1, 32, 32, and 64 μg/ml, respectively. In a separate study,

Table 36.5 Interpretive criteria for macrolides and lincosamides used in animals. Source: Data from CLSI, 2015.

		MIC Interpretive Category (µg/ml)			
Drug	**Species**	**S**	**I**	**R**	**Comments / Pathogens**
Erythromycin	Humans	≤ 0.5	1-4	≥ 8	Human *Staphylococcus*. No criteria available for animals.
	Humans	≤ 0.25	0.5	≥ 1	Human *Streptococcus*. No criteria available for animals.
Azithromycin	Humans	≤ 0.5	1	≥ 2	Human only. No criteria available for animals.
Tilmicosin	Bovine	≤ 8	16	≥ 32	Bovine respiratory pathogens.
	Swine	≤ 16	–	≥ 32	Swine respiratory pathogens
Tulathromycin	Bovine	≤ 16	32	≥ 64	Bovine respiratory pathogens (*Mannheimia, Pasteurella,* Histophilus)
	Swine	≤ 16	32	≥ 64	*Pasteurella multocida, Bordetella bronchiseptica*
		≤ 64	–	–	*Actinobacillus pleuropneumoniae*
Tildipirosin	Bovine	≤ 8	16	≥ 32	Bovine respiratory pathogens (*Histophilus, Pasteurella*)
		≤ 4	8	≥ 16	Bovine respiratory pathogens (*Mannheimia*)
	Swine	≤ 8	–	–	*Bordetella bronchiseptica*
		≤ 4	–	–	*Pasteurella multocida*
		≤ 16	–	–	*Actinobacillus pleuropneumoniae*
Gamithromycin	Bovine	≤ 4	8	≥ 16	Bovine respiratory pathogens. (*Mannheimia, Pasteurella*, Histophilus)
Clindamycin	Canine	≤ 0.5	1-2	≥ 4	*Staphylococcus* spp. *Streptococcus* spp.

S, susceptible; R, resistant; I, intermediate.

gamithromycin had a MIC_{90} of 1 µg/ml (Berghaus et al., 2012). Therefore, all macrolides are not alike with respect to their activity against this equine pathogen.

The CLSI (CLSI, 2015) standards and interpretive categories are shown in Table 36.5 for susceptibility testing. As shown in this table, drugs in this class vary in their potency and activity against various pathogens. Because of their targeted use, most of this data were generated for respiratory pathogens (Watts, 1999).

Pharmacokinetic–Pharmacodynamic Properties

The PK/PD properties of macrolides have been more difficult to define compared to other antimicrobials. Plasma concentrations, especially for the newer, long-acting agents (Table 36.6) are often below the MIC of pathogens for most, or all of the dose interval. Therefore, parameters such as peak above MIC (C_{max}/MC) or time above MIC (T>MIC) cannot be used to predict efficacy. Efficacy is probably best attributed to the concentrations at the site of infection – the pulmonary epithelial lining fluid (PELF). Although concentrations in the PELF have been reported from many studies in research animals (Guigère and Tessman, 2011; Villarino et al., 2013), this fluid is difficult to sample routinely in clinical cases. Therefore, the plasma drug concentration has been examined as a surrogate marker for efficacy from administration of macrolides and their derivatives. The parameter that is best suited to predict efficacy is the AUC of the plasma drug concentration to MIC (AUC/MIC) ratio (Drusano, 2005; Toutain et al., 2017). It has been suggested that the high concentrations in inflammatory cells deliver high concentrations to infected site and this effect is responsible for the efficacy in infected tissues. However, as summarized in the review by Villarino et al. (2013), citing studies by their laboratory and others, the concentrations contained in these cells are not likely high enough to contribute significantly to the PK/PD properties of the macrolides. This view was supported by the analysis by Toutain and associates (Toutain et al., 2017).

The magnitude of the AUC/MIC target has emerged from laboratory animal studies and analysis of clinical results. The azithromycin free serum AUC/ MIC for a 24-hour interval (AUC_{24}) ratio of >25 has been suggested from a mouse thigh infection model reported by Craig et al. (2002). However, this ratio is likely lower in non-neutropenic animals and Rodvold et al. (2003) suggested plasma AUC_{24}/ MIC ratios of at least 10 in nonneutropenic hosts with pneumonia, and higher AUC_{24}/ MIC ratios of 25–30 for worst case scenarios with experimental neutropenia. The study by Sevillano et al. (2006) showed that a serum azithromycin AUC_{24}/MIC ratio of approximately 27 was adequate for sustained bactericidal activity against susceptible strains. The analysis by Toutain and colleagues cited earlier supported a AUC_{24}/MIC value of approximately 24 for tulathromycin treatment of pneumonia in calves (Toutain et al., 2017).

Because most of the newer macrolides have long half-lives and produce concentrations for much longer than 24 hours, some investigators have considered the AUC values for the duration of treatment, rather than limited to 24 hours. In the study by Muto et al. (2011), using this approach, the AUC/MIC ratio >5 for azithromycin was associated with successful clinical outcome. If one examines the pharmacokinetics from studies of the

[a] For some studies, half-life was not reported and mean residence time (MRT) is listed in the table.

[b] For some studies, the volume of distribution was from a nonintravenous route and is listed as Vd/F.

[c] Data listed for clarithromycin by Peters et al., (2011, 2012), and Berlin et al., (2016) is without coadministration of rifampin. Administration of rifampin with clarithromycin lowers the concentration by 70% to over 90%. These values are provided in detail in those papers.

[d] Data referenced for Villarino et al. (2013) are an average of multiple studies reported in their paper.

long-acting macrolides listed in Table 36.6, AUC/MIC ratios of 5–10 for gamithromycin, azithromycin, and tildipirosin have been associated with clinical success. Tildipirosin, which has a longer half-life, produces a ratio of approximately 24. The study by DeDonder et al. (2016) showed that for gamithromycin administration to feeder cattle with bovine respiratory disease associated with *Mannheimia haemolytica* or *Pasteurella multocida*, the AUC infinity/MIC ratio associated with clinical success in these cases was 3.49 (*Mannheimia haemolytica*) and 3.21 (*Pasteurella multocida*).

Immunomodulatory Effects

Virulence properties of some bacteria may be inhibited by macrolides at concentrations that are less than the MIC required for inhibition or killing. This property, along with the effects on immunomodulation described in more detail below, may explain many of the benefits of macrolides for treating pneumonia (Kovaleva et al., 2012).

The macrolides, particularly the ones that concentrate in immune cells (Figure 36.3) have multiple immunomodulatory effects that likely contribute to the therapeutic response in respiratory infections, and perhaps other diseases. Beneficial effects may be produced by enhanced degranulation and apoptosis of neutrophils and inhibition of inflammatory cytokine production. Enhanced macrophage functions may also may help clear infections faster. These properties have been studied for azithromycin (Parnham et al., 2014) and for the veterinary drugs tilmicosin and tulathromycin (Chin et al., 2000; Duquette et al., 2015). As these reviews and studies point out, there is likely an immunomodulatory effect of these agents that contributes to the therapeutic benefits that is independent of the direct effect on bacteria. These drugs have been known to produce therapeutic benefits in patients even when the bacteria have MIC values in the range that is considered resistant, and above achievable concentrations in plasma or the epithelial lining fluid of the respiratory tract. The authors of these studies are careful to point out that the effect of macrolides is best termed *immunomodulatory* rather than immunosuppressive, which implies that it may modify or regulate functions of the immune system without impairing normal responses to combat bacterial infection (Kanoh and Rubin, 2010). According to Kanoh and Rubin (2010) the 14- and 15- membered macrolides exert these immunomodulatory effects, but not 16-membered macrolides. However, tilmicosin, a 16-membered ring macrolide (Figure 36.3, Table 36.4) also exhibits some of these properties (Chin et al., 2000).

As reviewed by others (Parnham et al., 2014; Kanoh and Rubin, 2010; Giamarellos-Bourboulis, 2008) macrolide antibiotics have shown inhibition in models of inflammation. These mechanisms include inhibition of inflammatory cells, improved epithelial function, and attenuated expression of inflammatory mediators. These properties have led to the recommended use of macrolides to treat some inflammatory diseases in people (Giamarellos-Bourboulis, 2008; Kanoh and Rubin, 2010). Because macrolides attain high concentrations in leukocytes and remain for a long time, primarily in lysosomes, there may be a biphasic response whereby initially the macrolides activate neutrophils and produce an initial burst that increases antibacterial activity, followed by suppression of inflammatory mediators and increased neutrophil apoptosis.

Pharmacokinetics

Absorption and Distribution

Erythromycin pharmacokinetics has been studied in most animals and in humans; some of these parameters are shown in Table 36.7. Tylosin pharmacokinetics in some animals is shown in Table 36.8. Oral erythromycin is discussed in more detail below in the section on erythromycin and summarized in Table 36.7. Tylosin has good absorption from the gastrointestinal tract, and no enteric coating is required to maintain the stability of the compound in the stomach. It is widely distributed to basically the same tissues as described for erythromycin, metabolized by the liver, and excreted via the bile and feces.

Oral absorption of most of the newer macrolides (Table 36.4) is not an issue because these are injected. For the others, oral absorption is moderate, but depends on the species. Azithromycin was absorbed 56% (Jacks et al., 2003) or 39% (Davis et al., 2002) in foals. It was absorbed 52% in cats (Hunter et al., 1995) and 97% in dogs (Shepard and Falkner, 1990). Clarithromycin was absorbed 57% in foals (Womble et al., 2006) and 71% in foals (Vilmànyi et al., 1996).

SC or IM injections of erythromycin can be painful and irritating; therefore, the PO route is preferred whenever possible. The only formulations that can be given IV are the glucoptate and lactobionate forms, because these are the only forms soluble in aqueous solution.

Pharmacokinetics of the newer macrolides are shown in Table 36.6. These properties have been extensively studied in many domestic animals. They have also been examined in several exotic and zoo animals (not shown in the table). These macrolides are characterized by much longer terminal half-lives compared to erythromycin. These long half-lives allow for intermittent administration (for example every-other-day in foals), and a single administration for gamithromycin, tildipirosin, tilmicosin, and tulathromycin in pigs and cattle. The volumes of distribution are very large, often in excess of 10 l/kg, and as high as 49 l/kg. The high volume of distribution is attributed to the extensive distribution to intracellular sites in tissues. Many of the studies referenced in Table 36.6 also reported tissue concentrations.

Macrolides tend to concentrate in some cells because the basic drug is trapped in cells that are more acidic than plasma. Tissue concentrations for macrolides, especially the newer azalides (Figure 36.3) are higher than serum concentrations. High concentrations have been documented in the respiratory tract, where PELF, bronchoalveolar fluid (BAL), leukocycte, and alveolar macrophages are many fold higher than plasma drug concentrations, often exceeding 100 times plasma concentrations. It is likely that the high concentrations in the epithelial lining fluid of the airways contribute significantly to the clinical efficacy for preventing and treating pneumonia.

Protein binding for macrolides is low to moderate, with values of 18–30% for most species. Protein binding in

some species may be predominantly to the α-1-acid glycoprotein, rather than albumin (Kinoshita et al., 1995).

Metabolism and Excretion

Metabolism of erythromycin is by hepatic microsomal enzymes. For the other drugs, the metabolic pathway has been less well characterized. In people, most of azithromycin is excreted in the feces. Low concentrations are anticipated in the urine and kidney dysfunction is not expected to produce an appreciable effect on the elimination half-life in the body. Because of the low urine concentrations, lower activity at acidic pH, and spectrum of activity that does not favor Enterobacteriaceae, these agents are not a good choice for treating urinary tract infections (Sabath et al., 1968).

Adverse Effects and Precautions

When humans are treated with erythromycin, many adverse effects are reported, which include nausea and vomiting (oral forms), fever, skin eruptions, cholestatic hepatitis, elevated serum aspartate aminotransferase, epigastric distress, and transient auditory impairment, among many other side effects. Cholestatic hepatitis is associated with the estolate ester, with the symptoms starting 10–20 days after beginning therapy and ending a few days after the cessation of therapy. Cholestasis associated with erythromycin use in humans is considered to be a hypersensitivity reaction (Sande and Mandell, 1990a). In animals, these effects are less common. However, regurgitation and/or vomiting has been commonly reported in small animals, especially dogs after oral administration of erythromycin. In one report, erythromycin was the drug that most frequently caused side effects after oral dosing in dogs (Kunkle et al., 1995). Stimulation of gastrointestinal motility may play a role in small-animal vomiting (discussed in Section Clinical Use of Erythromycin to Modify Gastrointestinal Motility). Erythromycin has been associated with producing diarrhea in horses (Papich, 2003). Although these reactions in the horse may limit its use in some patients, it is still frequently used to treat infections in horses, especially in the foal. Hyperthermia (febrile syndrome) has been observed in foals associated with erythromycin treatment (Stratton-Phelps et al., 2000), which was accompanied in some foals by diarrhea and respiratory distress. Other adverse effects are discussed for specific agents in each section.

Drug Interactions

Erythromycin is a well-known hepatic microsomal enzyme inhibitor. Erythromycin is both a substrate and an inhibitor for the cytochrome P450 enzymes, which is the enzyme system that is most often involved in drug metabolism. As an inhibitor of the cytochrome P450 enzymes, it may inhibit metabolism of drugs such as theophylline, cyclosporine, digoxin, and warfarin. Concentrations of these drugs may increase when animals receive erythromycin, resulting in a potentiation of the pharmacological effect or toxicity.

Effects of the other macrolides on animal drug metabolism has not been investigated in much detail. Azithromycin can also be an enzyme inhibitor in people, but less so than for erythromycin. Nevertheless, concurrent use of any of the drugs in this class with other drugs that have a narrow therapeutic index should be monitored.

Erythromycin

Erythromycin is inactivated in the stomach due to gastric acidity, which is the reason that other formulations, such as erythromycin estolate or stearate forms or enteric-coated formulations, are used. These modified forms have better bioavailability owing to decreased destruction of erythromycin in the acidic environment of the stomach. Crushed tablets of enteric-coated preparations are substantially degraded in the stomach or are metabolized in the intestine wall and are not recommended for oral administration to animals. The presence of food in the stomach also tends to decrease absorption of erythromycin in most species, including the dog (Wilson, 1984; Eriksson et al., 1990). Erythromycin salts (erythromycin-stearate and erythromycin-phosphate) dissociate in the intestine and are absorbed as the active drug. Erythromycin esters (erythromycin-ethylsuccinate and erythromycin-estolate) are absorbed as the esters and hydrolyzed in the body to release active drug. There is no proven difference among these formulations as to which is the most favorable in most animals. However, in horses, it was shown that the salt forms (erythromycin phosphate or erythromycin stearate) are preferred for oral administration (Ewing et al., 1994) because they provided the most favorable blood concentrations. A series of studies by Lakritz et al. (1999, 2000a, 2000b, 2002) examined the absorption of various oral formulations in foals. The ethylsuccinate form was poorly absorbed, but the phosphate, estolate, and microencapsulated forms were better absorbed (16%, 14.7%, and 26%, respectively). Absorption was better in foals when food was withheld.

There are also oral formulations intended to be added to the feed or drinking water to treat infections for poultry. Examples of these preparations are erythromycin thiocynate premix and erythromycin phosphate powder (Ery-Mycin). Veterinary forms of erythromycin injectable (e.g., Erythro-100 and Gallimycin-100) are 100 mg/ml formulations intended for IM injection only; they should not be administered SC or IV. Doses of erythromycin are listed in Table 36.7. Erythromycin and other macrolide antibiotics are sometimes used as a penicillin alternative when penicillins have either failed or when there is allergy to penicillins. Infections treated by erythromycin include those caused by *Staphylococcus* spp., *Streptococcus* spp., *Arcanobacterium* spp., *Clostridium* spp., *Listeria* spp., *Bacillus* spp., *Erysipelothrix* spp., *Histophilus*, *Brucella* spp., *Fusobacterium* spp., *Pasteurella* spp., *Borrelia* spp., and *Mycoplasma* spp. Erythromycin has also been used as a treatment for undifferentiated bovine respiratory disease and for pig infections caused by *Erysipelothrix* and for pig respiratory infections caused by *Streptococcus* and *Pasteurella*. In poultry, erythromycin is used for treatment of respiratory infections caused by *Mycoplasma*. In foals, erythromycin is used, in combination with rifampin for treatment of pneumonia caused by *Rhodococcus equi*. However, there is some evidence that erythromycin administered alone may be equally efficacious. For this use in horses, azithromycin or clarithromycin have become more common (see Sections Azithromycin and Clarithromycin).

In small animals, erythromycin has been used to treat pyoderma caused by staphylococci (Noli and Boothe, 1999), respiratory infections caused by *Mycoplasma,* and diarrhea caused by *Campylobacter* organisms. However, because of pharmacokinetic studies in dogs and cats, inadequate oral absorption and need for frequent IV administration limits the practical use. When treating *Campylobacter,* erythromycin stopped the shedding but did not eliminate the organism. Respiratory infections have sometimes been treated with erythromycin, but other drugs (e.g., azithromycin) have become more common because of better spectrum, longer half-life, and fewer adverse gastrointestinal effects. Experience in cats has been very limited. Based on a pharmacokinetic study (Albarellos et al., 2011), the IV administration to cats had a very short half-life and effective concentrations sustained for only 1.5 hours. Intramuscular injections in cats produced pain at the injection site and would not be a practical route for repeated injections. Erythromycin in the ethylsuccinate form as tablets or oral suspension did not produce measureable serum concentrations (15 mg/kg) after oral administration to cats (Albarellos et al., 2011). In dogs the ethylsuccinate and estolate oral formulations were poorly absorbed (Albarellos et al., 2008). The half-life was also short and would require frequent administration. These finding raises doubt about the oral use of these formulations for treatment in dogs or cats.

Clinical Use of Erythromycin to Modify Gastrointestinal Motility

Although some nausea from oral erythromycin is possible, most of this effect is believed to be related to a drug-induced increase in gastrointestinal motility. This mechanism appears to be related to an increase in activation of motilin receptors, via release of endogenous motilin, or via cholinergic mechanisms in the upper gastrointestinal tract (Hall and Washabau, 1997; Lester et al., 1998). At small doses (1 mg/kg) erythromycin has been considered for use as a motility-stimulating drug in animals. In calves, administration of erythromycin, tylosin, or tilmicosin increased the rate of abomasal emptying, with erythromycin (8.8 mg/kg IM) producing the most significant effect (Nouri and Constable, 2007; Nouri et al., 2008; Wittek and Constable, 2005). In calves, these drugs increase the abomasal emptying rate and erythromycin (10 mg/kg IM) has been used to improve postoperative abomasal rate in dairy cows undergoing surgical correction of left abomasal displacement (Wittek et al., 2008). These properties of erythromycin are discussed in more detail in Chapter 46. Although 14-membered macrolides appear to have the most profound effect on the gastrointestinal tract (Table 36.4), there is also an effect from 16-membered macrolides such as tylosin and tilmicosin (Nouri and Constable, 2007).

Regulatory Considerations

Erythromycin has a 6-day withdrawal time when used according to label in cattle in the United States. Erythromycin added to feed or water for poultry has a withdrawal time of 1–2 days; the specific product label should be consulted for the exact withdrawal time. In the United States, erythromycin should not be administered to lactating dairy cattle because macrolides concentrate in the milk for a long time after treatment. However, Canadian labeling lists a milk withholding time of 72 hours after a dose of 2.2–4.4 mg/kg.

Tylosin

Pharmacokinetic data for tylosin are listed in Table 36.8. Tylosin has been used therapeutically to treat “pinkeye” (*Moraxella bovis*) in cattle; respiratory tract infections; swine dysentery; pleuropneumonia due to *Haemophilus parahemolyticus;* and other infections in cats, chickens (Ose and Tonkinson, 1985), quail (Jones et al., 1976), and turkeys (Wilson, 1984). Tylosin has been used more extensively as a feed additive in food-producing animals, such as swine, cattle, and chickens, among others (Wilson, 1984). Tylosin phosphate premix has been added to feed for cattle, pigs, or poultry, and tylosin tartrate (Tylan soluble) for the drinking water of poultry.

Residues from tylosin have been discussed in other papers (Knothe, 1977a, 1977b; Anderson et al., 1966). After administration to cattle there is a 21- and 14-day withdrawal time for slaughter for cattle and pigs, respectively. Tylosin concentrates in milk for a long time after administration and should not be administered to lactating dairy cattle. Specific product information should be consulted for withholding times when tylosin is administered in feed or water to pigs or poultry because withdrawal times can vary from 0 to 5 days, depending on the use.

Tylosin has also been used to treat diarrhea in dogs, which is discussed in Chapter 46 in more detail. This type of diarrhea has been characterized as "tylosin-responsive chronic diarrhea in dogs" (Westermarck et al., 2005). In these animals, tylosin has been effective at improving clinical signs that occur with or without organisms being identified.

Tilmicosin

Tilmicosin (Micotil) 300 mg/ml for SC injection (10–20 mg/kg) to cattle and sheep (10 mg/kg). Tilmicosin phosphate (Micotil 300) has been effective for treating bovine respiratory disease (Musser et al., 1996; Hoar et al., 1998; Jim et al., 1999). One study (Ose and Tonkinson, 1988) reports that 90% of the *Mannheimia haemolytica* and *Pasteurella multocida* isolates tested were susceptible to tilmicosin at concentrations of ≤6.25 μg/ml, and the drug was also active against *Mycoplasma,* including those from bovine isolates. Other organisms with in vitro susceptibility to tilmicosin include staphylococci and streptococci. Most gram-negative organisms other than those causing bovine respiratory disease are resistant.

Tilmicosin administered to calves with pneumonia were found to respond better when treated with 10 mg/kg SC tilmicosin than with a 20 mg/kg IM dose of oxytetracycline (Laven and Andrews, 1991). Like other macrolides, tilmicosin reaches high concentrations in lung tissues and this may account for efficacy treating bovine pneumonia (Gourlay et al. 1989). Resistance among cattle respiratory pathogens has been recognized (Musser et al., 1996), but treatment response in cattle with bovine respiratory disease was not associated with the MIC of the pathogens, and there was treatment success even when bacteria recovered had MIC values in the resistant range (McClary et al., 2011).

Tilmicosin also has been used as a prophylactic antibiotic (metaphylaxis) for administration to calves entering a feedlot situation. Tilmicosin reduced the incidence of pneumonia in susceptible calves when administered prophylactically as a single 10 mg/kg SC injection (Morck et al., 1993; Schumann et al., 1990). Tilmicosin used as a metaphylactic treatment in newly arrived feedlot calves reduced prevalence of bovine respiratory disease and improved growth of calves (Vogel et al., 1998).

The CLSI breakpoint (Table 36.5) for tilmicosin susceptibility is ≤8 μg/ml for cattle respiratory pathogens (*Mannheimia haemolytica*) and ≤16 μg/ml for swine respiratory disease pathogens. The currently approved dose is 10–20 mg/kg SC as a single treatment in cattle, and 10 mg/kg in sheep. After treatment with tilmicosin phosphate in cattle, there is a 28-day withdrawal time. Tilmicosin should not be administered to lactating dairy cattle because residues may persist in milk for more than 30 days.

Tilmicosin phosphate is approved for treatment of swine respiratory disease caused by *Actinobacillus pleuropneumoniae* and *Pasteurella multocida*. This form (Pulmotil) is administered as a feed additive and has been shown to be effective for controlling pneumonia in swine (Moore et al., 1996). There is a 7-day withdrawal time for slaughter when administered to swine.

Tilmicosin has also been used for treatment of pasteurellosis in rabbits (McKay et al., 1996). Single doses of 25 mg/kg SC were an effective treatment for pasteurellosis in rabbits.

Adverse Reactions to Tilmicosin

Injections of tilmicosin to horses, goats, swine, or nonhuman primates can be fatal. The heart is the target of toxicity in animals, perhaps mediated via depletion of cardiac intracellular calcium, resulting in a negative inotropic effect (Main et al., 1996). Epinephrine worsens the cardiac toxicity in pigs, but dobutamine has alleviated the cardiac depression in dogs (Main et al., 1996). The effects of toxicity are increased heart rate, arrhythmia, and depressed contractility. Injected doses of 20 and 30 mg/kg to pigs caused death, but oral tilmicosin in pigs produces no toxic effects. In cattle, injected SC doses of 50 mg/kg caused myocardial toxicity; 150 mg/kg was lethal. Doses as low as 10 mg/kg administered by the IV route have caused cardiac toxicity as well (Ziv et al., 1995).

The risk of cardiac toxicity is particularly important for humans. There are warnings on the tilmicosin label that accidental injection into humans has caused death. Published reports (Veenhuizen et al., 2006) indicate that several people have died as a result of tilmicosin administration.

Tulathromycin

The injectable formulation of tulathromycin (Draxxin) is 100 mg/ml for use as a single SC injection at 2.5 mg/kg. Tulathromycin is an azalide derivative of erythromycin, with three charged nitrogen groups; therefore it has been called a *triamilide* (Evans, 2005). These charged groups may be important to increase the intracellular concentrations compared to other macrolides. It is approved for use in cattle and pigs and has occasionally been used in other species. In cattle and pigs it is used for treating respiratory infections (bovine respiratory disease and swine respiratory disease), for which the pathogens have been discussed earlier in this chapter and CLSI breakpoints are listed in Table 36.5. In addition to these pathogens the label includes *Mycoplasma bovis* in this drug's indications. It is administered once (e.g., 2.5 mg/kg SC in cattle and IM in swine) and produces sustained drug concentrations in lung tissue for several days. It also is used to prevent bovine respiratory disease when administered to cattle (metaphylaxis) that are at risk for developing respiratory disease (Booker et al., 2007). Withdrawal times are 18 days for cattle and 5 days for swine. It has also been administered to other species and a dose of 2.5 mg/kg as a single injection has been used in other domestic food animals and zoo hoof stock.

There is limited evidence that tulathromycin may be useful for treating pulmonary infections in foals (Venner et al., 2007; Rutenberg et al., 2017). At 2.5 mg/kg IM once per week, it resolved pulmonary lesions and, except for diarrhea in some foals, was well tolerated. In a study of 240 foals endemic for infections caused by *Rhodococcus equi,* treated with 2.5 mg/kg IM, once per week, it was effective, but not as effective as the combination of azithromycin–rifampin (Rutenberg et al., 2017). However, it is less active than other agents against *Rhodococcus equi* and is not recommended (Giguère et al., 2011).

Clarithromycin

Clarithromycin (Biaxin®) is semisynthetically derived from erythromycin. It is primarily used in people because it is tolerated better than erythromycin, has a broader spectrum, and concentrates in leukocytes. Clarithromycin in combination with ranitidine and bismuth (Tritec®) is also used to treat *Helicobacter pylori* infections in people. In dogs, clarithromycin does not have pharmacokinetic features that are as favorable as those of azithromycin (the half-life is not as long) and the use is rare.

Most veterinary experience has been in foals, where clarithromycin has been investigated as a potential treatment for respiratory infections. It has more activity against *Rhodococcus equi* isolated from foals than other macrolides (Jacks et al., 2003; Riesenberg et al., 2014; Berghaus et al., 2013). In foals, clarithromycin is absorbed orally and has a half-life of 4–6 hours, depending on the study (Table 36.6). Not shown in Table 36.6 is the effect of coadministration of rifampin on clarithromycin concentrations in foals. Because of induction of enzymes and transporters, coadministration with rifampin decreases plasma drug concentrations by over 90%, which is discussed in more detail in Section Rifampin (Rifampicin).

The concentrations in the respiratory ELF, bronchial/alveolar epithelial cells, and BAL cells of foals is many fold higher than plasma drug concentrations – reaching levels that are over 30–40 times higher in the ELF and over 300–1800 times higher in BAL cells (Peters et al., 2011, 2012). However, the concentrations do not persist in tissues for as long as azithromycin (Suarez-Mier et al., 2007). Oral absorption in foals was 57% (Womble et al., 2006) and 41.5% (Berlin et al., 2016), compared to 70–75% in dogs. In foals, oral clarithromycin at a dose of 7.5 mg/kg every 12 hours produces concentrations sufficient for treatment of *Rhodococcus equi* infections (Jacks et al., 2002; Giguère et al., 2011). It has been more successful at this dose than azithromycin (Giguère et al., 2004). It is also metabolized in horses to 14-hydroxyclarithromycin, which is microbiologically active and contributes to the activity (Peters et al., 2011, 2012; Berlin et al., 2016).

Gamithromycin

Gamithromycin (Zactran) is a 15-membered ring (like azithromycin and tulathromycin). The mechanism of action is the same as other macrolides. Gamthromycin has a spectrum of activity that is limited to gram-positive bacteria and some gram-negative bacteria that cause respiratory diseases in cattle (e.g., *Mannheimia haemolytica, Mycoplasma,* and *Pasteurella multocida*). Susceptibility information and pharmacokinetics are listed in Tables 36.5 and 36.6. Like other long-acting macrolides, the half-life is long (Giguère et al., 2011, Table 36.6) with long persistence in lungs, which prolongs the drug concentration at the site of infection.

In cattle, several studies have established the efficacy of gamithromycin for treatment of bovine respiratory disease caused by *Mannheimia haemolytica, Pasteurella multocida*, *Histophilus somni*, and *Mycoplasma bovis* (Torres et al., 2013a, 2013b; Lechtenberg et al., 2011a, 2011b, 2011c, 2011d). In two studies it had a higher morbidity rate and retreatment rate than cattle treated with tulathromycin (Torres et al., 2013a, 2013b), but was otherwise equivalent. It is also effective for treating infections caused by *Mycoplasma bovis*. It also may be used for control of respiratory disease in beef and nonlactating dairy cattle at high risk of developing bovine respiratory disease (metaphylaxis) associated with *Mannheimia haemolytica* and *Pasteurella multocida*.

The MIC values for *Rhodococcus equi* are low and a IM dose of 6 mg/kg has been investigated for treatment of horses (Berghaus et al., 2012; Hildebrand et al., 2015). Even though it was effective in foals with bronchopneumonia, it had a higher incidence of adverse effects in foals that included colic and hind limb lameness. Almost 60% of treated foals showed reactions to the administration of gamithromycin.

Tildipirosin

Tildipirosin (Zuprevo) is a 16-membered ring (like tilmicosin) macrolide antimicrobial with three charged nitrogen atoms (like tulathromycin), which is currently limited to the treatment and control/prevention of bovine respiratory disease and the treatment of swine respiratory disease, although it has also been used for the control/prevention of swine respiratory disease. The mechanism of action is the same as for other macrolides. Pharmacokinetics and other properties were reported by Menge et al. (2012) and Rose et al. (2013). Tildipirosin has a spectrum of activity that is limited to gram-positive bacteria and some gram-negative bacteria that cause respiratory diseases in cattle and pigs (e.g., *Mannheimia haemolytica, Mycoplasma, Pasteurella multocida, Actinobacillus pleuropneumoniae, Bordetella bronchiseptica,* and *Haemophilus parasuis*). *Escherichia coli* and *Pseudomonas aeruginosa* are resistant. Some *Staphylococcus* spp. and *Streptococcus* spp. may be susceptible. There is evidence for bactericidal activity against *Mannheimia haemolytica*, bovine *Pasteurella multocida, Histophilus somni, Haemophilus parasuis,* and *Actinobacillus pleuropneumoniae*, but bacteriostatic activity against *Bordetella bronchiseptica*.

Pharmacokinetics in cattle (Table 36.6) shows that the half-life is long and bioavailability from injection in cattle is 79%. The volume of distribution is larger than other macrolide antibiotics, with a volume of distribution in cattle of 49 l/kg. The lung concentrations in cattle are over 150 times the plasma drug concentrations, with a half-life of 10 days. Bronchial fluid concentrations are approximately 40 times the plasma drug concentrations, with a half-life of 11 days.

In pigs, the plasma half-life is 106 hours (4.4 days), with a peak concentration of 0.9 μg/ml after IM injection of 4 mg/kg. The lung concentrations in pigs were approximately 80 times higher than plasma concentrations, with a half-life of 6.8 days. The bronchial fluid concentrations were 680 times higher than plasma drug concentrations at 5 days after injection. Tildipirosin, like other macrolides, exerts therapeutic benefits not solely explainable by antibacterial activity and may have immunomodulatory effects.

Tildipirosin has been approved for the treatment and control/prevention of bovine respiratory disease associated with *Mannheimia haemolytica, Pasteurella multocida,* and *Histophilus somni* and in some European countries for the treatment of swine respiratory disease associated with *Actinobacillus pleuropneumoniae, Pasteurella multocida, Bordetella bronchiseptica,* and *Haemophilus parasuis*.

Azithromycin

Azithromycin (Zithromax®) is the first drug in the class of azalides approved for people, but it also is administered frequently to small animals, exotic species, and horses. Azithromycin has better oral absorption, is better tolerated, has a much longer half-life (especially in tissues), and has a broader spectrum of activity than erythromycin.

Azithromycin is active against gram-positive aerobic bacteria (staphylococci and streptococci) and anaerobes. However, the activity against staphylococci is not as good as erythromycin. It has some activity against gram-negative bacteria such as *Haemophilus* but limited activity against enteric gram-negative bacteria, and ineffective against *Pseudomonas aeruginosa*. It has activity against many intracellular organisms, including *Chlamydophilia* (formerly called *Chlamydia*) and *Toxoplasma.* It is also active against mycobacteria and *Mycoplasma* (Lode et al., 1996).

The primary pharmacokinetic difference between azithromycin and erythromycin is the long half-life and high concentration in tissues. Pharmacokinetic properties are shown in Table 36.6. Azithromycin reaches high concentrations in tissues, particularly leukocytes, macrophages, and fibroblasts. The tissue concentration can be as much as 100 times serum concentrations and concentrations in leukocytes can be at least 200–300 times the concentrations in serum (Panteix et al., 1993). In cats, the serum half-life is 35 hours, tissue half-lives vary from 13 to 72 hours, and the volume of distribution is 23 l/kg (Hunter et al., 1995). In dogs, it also exhibits rapid uptake and persistent concentrations in tissues; the volume of distribution is 12 l/kg, and plasma and tissue half-lives are 29 and 90 hours, respectively (Shepard and Falkner, 1990). Oral absorption is high, with bioavailability values of 58% in cats (Hunter et al., 1995) and 97% in dogs (Shepard and Falkner, 1990). In people, azithromycin is absorbed much better on an empty stomach (Lode et al., 1996) but the effect of feeding on oral absorption has not been explored in cats or dogs.

There also is interest in administering azithromycin to horses (Davis et al., 2002; Jacks et al., 2002, 2003; Suarez-Mier et al., 2007). Davis et al. (2002) showed that oral absorption was 39% and had a plasma half-life of 18 hours in foals. More importantly, the drug persisted in leukocytes and alveolar macrophages for at least 120 hours after a single dose at concentrations greater than 5.0 μg/ml, with a half-life in leukocytes of over 49 hours. As in other species, concentrations in PMNs were over 200 times the plasma concentrations. It had a volume of distribution in horses of 12 l/kg, which probably accounts for the long persistence in inflammatory cells.

Like other long-acting macrolide antibiotics, azithromycin produce high concentrations in tissues and leukocytes, even after the plasma concentrations have declined below detectable levels (Girard et al., 1990). Intracellular stores of azithromycin in leukocytes also can serve as a mode of delivery of azithromycin to infected tissues, especially early abscesses, since the leukocytes are attracted to these sites via chemotaxis (Girard et al., 1993). The immunomodulatory effects of azithromycin have been studied extensively and discussed previously in this chapter (Parnham et al., 2014). Beneficial effects of azithromycin are attributed, in part, to these effects on inflammatory cells and immune function.

Clinical Use of Azithromycin

Azithromycin has become popular for treating infections in dogs, cats, exotic animals, and birds. Results of treatment of intracellular infections caused by *Toxoplasma* spp. and *Mycobacterium* spp. have been conflicting in people and are not yet reported for animals. Because of the long half-life and persistence of drug in tissues, the regimen employed in people is to administer a dose once daily for 3–5 days. Thereafter, effective drug concentrations are expected in tissues for up to 10 days. In dogs, doses of 5–10 mg/kg once daily orally for 1–5 days have been suggested. In cats, doses of 5–10 mg/kg once daily or every other day or one dose two to three times a week orally have been used.

Despite the popularity of azithromycin for treatment of infections in dogs and cats, there is little clinical evidence published to demonstrate benefits over other drugs. In shelter cats with upper respiratory infections, it was no better than amoxicillin for treatment (Ruch-Gallie et al., 2008). In cats with chlamydophilosis (*Chlamydophila felis*) it was ineffective for clearing the infection. In dogs it has been effective for some skin infections based on limited reports, but was not as effective as other agents for treatment of Rocky Mountain spotted fever (*Rickettsia rickettsii*) (Breitschwerdt et al., 1999).

There are several reports of azithromycin clinical use in foals with pulmonary infections, such as those caused by *Rhodococcus equi.* Because of favorable pharmacokinetics, cited above, plasma, leukocyte, and alveolar macrophage concentrations persist long enough to allow for every-other-day administration. Based on this work the dose for foals is 10 mg/kg every 24 hours initially, followed by treatment every 48 hours orally. When azithromycin was administered orally to foals (10 mg/kg every 48 hours) it effectively reduced the pneumonia attributed to *Rhodococcus equi* (Chaffin et al., 2008). The use of azithromycin and other macrolides for treatment of *Rhodococcus equi* infections in foals was summarized in an ACVIM Consensus Statement (Giguère et al., 2011).

Safety of Azithromycin

Azithromycin is generally well tolerated. In people, gastrointestinal disturbances are the most common side effects (nausea, vomiting, diarrhea, abdominal pain). In dogs, high doses may cause vomiting. From the clinical reports, it appears to have been well tolerated in foals but transient diarrhea is possible. Adult horses may be more prone to developing diarrhea and more caution is urged with clinical use in these animals.

Erythromycin is well known to decrease the activity of drug-metabolizing enzymes in the liver. This can increase the toxicity of some drugs administered concurrently. Although azithromycin is reported to have less effect on the hepatic enzymes, some caution is needed when combining azithromycin with other drugs.

Lincosamide Antibiotics

Lincosamides are a group of monoglycoside antibiotics containing an amino acid-like side chain. There are two antibiotics within this group: lincomycin and clindamycin. Lincomycin and clindamycin are structurally similar. Lincomycin has a hydroxyl moiety at the 7 position of the molecule, and clindamycin contains a chlorine at this position (Figure 36.4), making

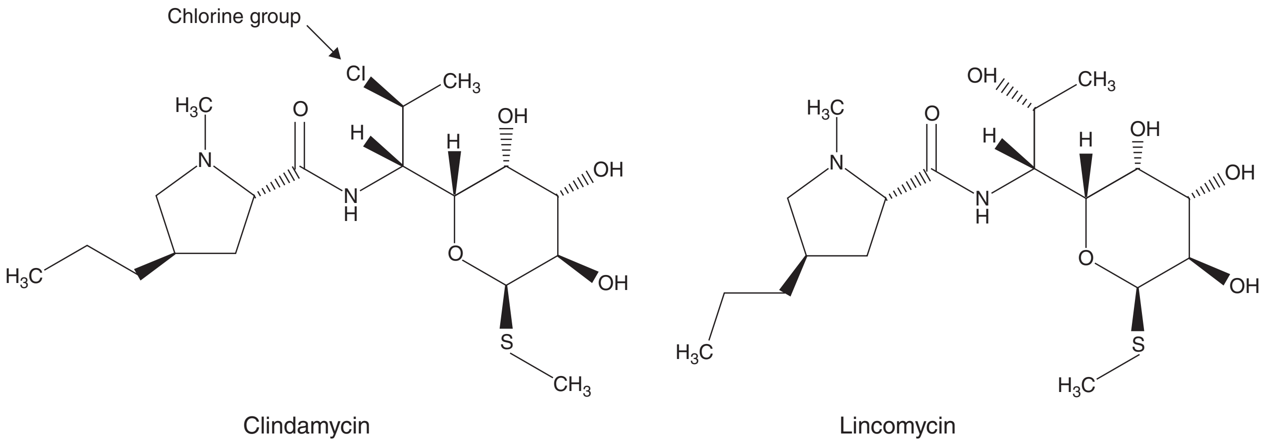

Figure 36.4 The chemical structures of clindamycin (left) and lincomycin (right). Structural difference is in the chlorine group on clindamycin.

clindamycin a more active molecule against bacteria than its parent molecule, lincomycin, and better absorbed orally. The lincosamides, like the macrolides, are used primarily to treat gram-positive infections in cases where there is resistance or intolerance to penicillins. Clindamycin also is a common drug for treatment of anaerobic infections. Common infections treated with lincosamides include infections involving *Staphylococcus* spp. and *Streptococcus* spp. (Burrows, 1980).

Lincomycin

Source and Chemistry

Lincomycin is the antibiotic produced by *Streptococcus lincolnensis* var. *lincolnensis,* discovered in the 1950s; its name comes from cultures of soil that originated in Lincoln, Nebraska. Veterinary formulations were first developed in the 1960s. Lincomycin is a weak base with a pK_a of 7.6 (Riviere et al., 1991).

Formulations

Lincomycin is available as an oral premix for pigs and chickens (Lincomix) and a soluble powder for drinking water (Lincomix). Lincomycin hydrochloride oral syrup and tablets have been used for dogs and cats (Lincocin), as well as lincomycin hydrochloride injection, but use in small animals is not as common as it once was. Ruminants and horses should not be exposed to lincomycin-supplemented feed. The toxicity is described in Section Adverse Effects and Precautions. There has been combination products of lincomycin and spectinomycin available in the past (for example Linco-Spectam), but this product has been discontinued in many countries. Veterinarians should consult local availability in each country of use.

Mechanism of Action and Spectrum

Lincomycin inhibits protein synthesis in the microbial cell by binding to the 50S ribosomal subunit in much the same way described for macrolides. Other antibiotics, such as erythromycin and clindamycin, function similarly by binding at different sites to the same ribosomal subunit. The spectrum of activity is similar for macrolides and lincosamides, with exceptions listed for individual drugs in this chapter. Bacteria with resistance to macrolides usually show cross-resistance to lincosamides. Macrolides and lincosamides should not be used together because this may produce a decrease in the overall efficacy against the microbe due to one bound antibiotic physically overlapping the binding site of another (Burrows, 1980).

Absorption and Distribution

Lincomycin is rapidly but incompletely absorbed when administered orally to animals, with one report stating that lincomycin oral absorption in swine given 10 mg/kg is in the range 20–50% (Hornish et al., 1987). Peak serum levels in most animals are reached within 60 minutes after an oral dose and within 2–4 hours after IM injection. Lincomycin is well distributed in the body, with highest tissue concentrations in the liver and kidneys, while very low levels are obtained in the CSF (Burrows, 1980; Ford and Aronson, 1985; Kleckner, 1984). The Vd in animals ranges from 1 to 1.3 l/kg.

Metabolism and Excretion

The half-life after oral, IM, or IV administration is approximately 2–4 hours. Most of the oral dose, measured as ^{14}C-labeled lincomycin, was recovered in the feces and 14% in the urine after a single oral administration to the dog (Kleckner, 1984); thus, biliary secretion of lincomycin appears to be an important route of elimination. After a single IM injection, 38% of the dose was found in the feces and 49% in the urine of the dog. Urine excretion of the radiolabeled drug was complete in 24 hours and fecal excretion was complete within 48 hours for both dosing routes. It is not known whether this radioactivity was associated with an unchanged/unmetabolized lincomycin or with the metabolites of this compound. An unpublished report cited by Hornish et al. (1987) stated the parent drug was the primary form present in the urine of dogs and humans.

Because of the potential for residues in meat, the metabolism and excretion of lincomycin have been studied more extensively in swine and chickens (Hornish et al., 1987). Lincomycin concentrations are highest in the liver and kidney, with low, albeit detectable, levels in muscle and skin. Lincomycin can pass unchanged from the body via the bile and feces or urine or can be metabolized to the glucuronide, *N*-demethyl lincomycin, or lincomycin sulfoxide forms by the liver. Swine given oral doses of lincomycin showed that 11–21% was excreted into the urine: 50% unchanged lincomycin, trace amounts of *N*-demethyl lincomycin, no lincomycin sulfoxide or glucuronide forms, and the rest labeled “unidentified substances.” The feces contained the remainder of the excreted lincomycin: 17% unchanged lincomycin, possible trace amounts of lincomycin sulfoxide, and 83% uncharacterized metabolites (Hornish et al., 1987). Similarly conducted studies in chickens treated orally for 7 days with lincomycin showed that the excreta contained ≈80% lincomycin, ≤10% lincomycin sulfoxide, ≤5% *N*-demethyl lincomycin.

Adverse Effects and Precautions

Dogs and cats have few adverse reactions to lincomycin. Loose stools in the dog and vomiting in the cat have been the major side effects reported (Kleckner, 1984). Pigs may occasionally develop diarrhea and/or swelling of the anus within the first 2 days of treatment and will self-correct within a week after withdrawal from the antibiotic.

The most serious adverse effect from lincomycin reported in people is that of pseudomembranous colitis. This is a serious disease in people caused by an overgrowth and production of toxin from *Clostridium difficile,* which may be fatal. In animals with fermenting gastrointestinal tracts (horses, ruminants, rabbits, hamsters, chinchillas, and guinea pigs) there also is a high risk of gastrointestinal bacterial overgrowth with *Clostridium* spp. from lincomycin treatment. Severe enteritis, enterocolitis, may lead to diarrhea and death. Other bacteria also have been implicated in this reaction, such as *Salmonella* spp. or *E. coli* (Burrows, 1980; Plenderleith, 1988). Lincomycin-induced enterocolitis has been reported for rabbits (Maiers and Mason, 1984; Thilsted et al., 1981; Rehg and Pakes, 1982), horses (Raisbeck et al., 1981; Plenderleith, 1988), sheep (Bulgin, 1988), and large ruminants (Plenderleith, 1988). Lincomycin has been reported to produce ketosis in dairy cows (Rice and McMurray, 1983).

Clinical Use

There are 85 products listed on the FDA list of approved drugs for animals. These products are in oral and injectable form for pigs, dogs, cats, and poultry. Lincomycin is used to treat gram-positive aerobic and anaerobic infections in patients for many of the same indications for which one would use erythromycin or other macrolides. In dogs and cats, lincomycin has been used to treat penicillin-resistant or suspected penicillin-resistant strains of *Staphylococcus* spp. and *Streptococcus* spp. bacteria found in bone, the upper respiratory tract, and the skin. Although it has been used for skin infections, it is not as popular as it once was (Noli and Boothe, 1999). Oral doses in dogs and cats generally are 22 mg/kg every 12 hours orally. The use of lincomycin to treat bacterial infections in dogs and cats has been largely replaced by clindamycin therapy (see Section Clindamycin).

Lincomycin has been utilized to treat bacterial arthritis in swine caused by *Staphylococcus* spp., *Streptococcus* spp., *Erysipelothrix* spp., and *Mycoplasma* spp., and pneumonia caused by *Mycoplasma* spp. Lincomycin has been added to the feed and water to control swine dysentery and *Mycoplasma* infections (Rainier et al., 1980; Hamdy, 1978; Hamdy and Kratzer, 1981). Injections have been administered to pigs for *Mycoplasma* infections (11 mg/kg every 24 hours IM). In cattle and sheep lincomycin has been injected IM for treatment of septic arthritis and mastitis and to control *Mycoplasma* infections. It should never be administered orally to these animals because of risk of inducing enteritis.

In broiler chickens, lincomycin has been used as a feed additive to increase the rate of weight gain and improve feed efficiency (this use has been phased out in the United States), in addition to treating necrotic enteritis in this species. The addition of 2 g/ton of lincomycin to the feed of broilers resulted in a significant decrease in the incidence of necrotic enteritis (Maxey and Page, 1977). Lincomycin has also been used with success in psittacines (Mandel, 1977). Lincomycin use in the eyes of rabbits has also been reported (Kleinberg et al., 1979). Topical corneal administration of 1% lincomycin in water to rabbits showed local therapeutic levels could be maintained from 30–45 minutes to 2 hours postdose in the cornea, aqueous humor, and iris-ciliary body and that deepithelialization of the corneal epithelium served to enhance the ocular topical absorption of this antibiotic.

Sheep, goats, and calves have been treated with parenteral lincomycin–spectinomycin antibiotic combinations for gram-positive and gram-negative respiratory tract infections. The lincomycin–spectinomycin combination (Linco-Spectam, 50 mg lincomycin with 100 mg spectinomycin per ml) at a dose of 1 ml/10 kg body weight IM has been used to treat foot rot in sheep caused by *Bacteroides nodosus* with better success than systemic penicillin–streptomycin therapy (Venning et al., 1990). However, in many countries the combination product of lincomycin–spectinomycin has been discontinued (see the discussion in section Spectinomycin).

Regulatory Considerations

When added to feed for poultry and pigs, the slaughter withdrawal time ranges from 0 to 6 days, depending on the preparation and dose. When injected in pigs, the withdrawal time for slaughter is 2 days. Because a large number of products are listed on the FDA approved drug list, consult the package insert for specific recommendations.

Clindamycin

Source and Chemistry

Clindamycin chemically is 7-chlorolincomycin, a derivative of lincomycin and an antibiotic produced by *Streptococcus lincolnensis* var. *lincolnensis*. The replacement of the hydroxyl group at the C7 position of the lincomycin molecule by a chloride results in a more active antibacterial effect when compared to lincomycin. The chemical structure of clindamycin is shown in Figure 36.4. It is a weak base with a pK_a of 7.6. Both clindamycin hydrochloride (HCl) and clindamycin palmitate are for oral administration. Clindamycin HCl is directly active when administered, whereas the palmitate form must be converted to clindamycin in the small intestine. Clindamycin palmitate is more palatable than clindamycin HCl. Clindamycin phosphate is the parenteral form of clindamycin and must undergo hydrolysis in the plasma for it to become active.

Mechanism of Action and Resistance

Clindamycin exerts its antibiotic activity by inhibiting protein synthesis at the 50S ribosomal subunit (Hedstrom, 1984) in a manner identical to that described for lincomycin. Resistance to clindamycin is most often caused by methylation of the 23S rRNA, which is the same mechanism that is most common for macrolide antibiotics. This mechanism of resistance is mediated by *erm* genes. Bacteria carrying these genes can be resistant to both macrolides and clindamycin. The other mechanism of resistance for macrolides is the efflux pump mediated by the *mef* gene. Clindamycin is not affected by this gene. Although modification of the 23S ribosome is the most common mechanism of resistance, if bacteria are resistant to macrolides because of the efflux pump mechanism, they may still be susceptible to clindamycin. The third mechanism of resistance, enzymes directed at the drug, is uncommon. Bacteria resistant to lincomycin are also resistant to clindamycin.

Spectrum of Activity

The chlorine substitution (Figure 36.4) produces higher activity against some bacteria than lincomycin. Clindamycin has been reported to be as much as 20 times more potent than lincomycin in the treatment of *Staphylococcus* and *Streptococcus* infections in humans (Harvey, 1985). Clindamycin is active against aerobic species of organisms, including *Staphylococcus, Streptococcus, Actinomyces, Nocardia, Mycoplasma,* and *Toxoplasma*. Because macrolide efflux is the predominant mechanism of macrolide resistance for *Streptococcus* spp., clindamycin remains active against most streptococci because they are not affected by this mechanism. The anaerobic bacterial spectrum of activity includes *Bacteroides fragilis, Fusobacterium* spp., *Peptostreptococcus* spp., and *Clostridium perfringens* (Harari and Lincoln, 1989). Clindamycin is not active against aerobic and facultatively anaerobic gram-negative bacilli such as the Enterobacteriaceae or *Pseudomonas* spp. *Pasteurealla* spp. (gram-negative aerobe) isolated from bite wounds of small animals are usually resistant to clindamycin.

Although most staphylococci are susceptible to clindamycin, approximately 25–36% of *Staphylococcus* spp. may be resistant to clindamycin, depending on the study and region from which the bacteria were isolated. Most methicillin-resistant *Staphylococcus pseudintermedius* (MRSP) isolated from dogs are resistant to clindamycin. On the other hand, many community-acquired methicillin-resistant *Staphylococcus aureus* may be susceptible to clindamycin.

In small animals, anaerobic infections are one of the major uses of clindamycin. One report (Jang et al., 1997) indicated that 83% of *Bacteroides* from small animals were susceptible to clindamycin and 80% of the *Clostridium.* Clindamycin resistance among *Bacteroides* is mediated by the *erm* gene and increased rates of resistance among anaerobes may reflect the prevalence of this gene. Most *Fusobacterium* spp. are also susceptible to clindamycin. An additional organism for which there is activity is *Toxoplasma,* but the clinical use of clindamycin for treating toxoplasmosis in cats is controversial (described in more detail in Section Clinical Use).

The CLSI breakpoint for susceptibility testing is ≤0.5 μg/ml, 1–2 μg/ml, and ≥4 μg/ml for susceptible, intermediate, and resistant categories, respectively (CLSI, 2015). Clindamycin may be used to test for lincomycin susceptibility, although clindamycin may be more active against some staphylococci than lincomycin.

Pharmacokinetics – Pharmacodynamics

Clindamycin exerts a bacteriostatic rather than a bactericidal effect on bacteria; therefore, it is important to maintain the plasma drug concentration above the MIC throughout the dose interval. The area-under-the-curve (AUC) to MIC ratio (AUC/MIC) for the free drug concentration is the best predictive parameter for clindamycin efficacy. The AUC/MIC target for a bacteriostatic effect is approximately 25. Protein binding is 92–95% in dogs and 91.5–94.5% in cats (protein binding tends to be lower at high concentrations ranging from 0.5 μg/ml to 5 μg/ml). Therefore, PK/PD calculations should use the free drug fraction (fraction unbound).

Absorption and distribution: Clindamycin is better absorbed from the gastrointestinal tract than lincomycin, yielding higher plasma concentrations (Nichols and Keys, 1984). Unlike lincomycin, the presence of food does not appear to affect oral absorption of clindamycin. Oral absorption was 73% in dogs after capsule administration and highly absorbed from IM injection (87%). When injected SC, the absorption is slow, producing a “flip-flop” effect and a longer half-life. Other pharmacokinetics are shown in Table 36.9. At doses administered to cats (Brown et al., 1989, 1990) 5.5 and 11.0 mg/kg oral doses maintained a serum MIC above that necessary for most *Staphylococcus aureus* infections and that the 11.0 and 22.0 mg/kg doses gave serum concentrations above the MIC for many susceptible anaerobes. Cats may be reluctant to accept the oral liquid form of clindamycin because of poor palatability.

In one study, it was reported that clindamycin is too painful for IM administration (Budsberg et al., 1992), but in another study, IM administration of a buffered, more concentrated 20% solution was better tolerated. SC administration may be better tolerated than IM injections (Lavy et al., 1999).

Little is known in most exotic or zoo species, but in sea turtles clindamycin had extremely rapid clearance and a short half-life. There was very little oral absorption.

Table 36.9 Pharmacokinetics of clindamycin in animals

Species	Dose (mg/kg)	Half-life (hour)	Volume of distribution (Vd) (l/kg)[b]	AUC (μg h/ml)	Peak Concentration (C_{max}) (μg/ml)	Reference
Cats	11–33 oral	9.02	3.75	31-42 at 11 mg/kg	6.6-7.4 at 11 mg/kg	Boothe et al., 1996; Brown et al., 1989[a]
	5.5 oral	4.25	–	6.7	1.9	Saridomichelakis et al., 2011
	11 oral	9.92	–	18.35	3.3	Saridomichelakis et al., 2011
	11 IV	3.24	1.5	34.99	–	Budsberg et al., 1992
	11 IM	3.91	–	35.7	5.3	Budsberg et al., 1992
	10 IV	2.1	1.23	24.28	–	Lavy et al., 1999
	10 IM	7.1	–	30.1	4.4	Lavy et al., 1999
Dogs	10 SC	5.2	–	87.63	20.8	Lavy et al., 1999

[a] Data represents a mean of the published values.
[b] Values for Vd represent Vd/F for oral doses.

These results in sea turtles suggest that it would be impractical to use in these animals (Harms et al., 2011).

In dogs and cats the volume of distribution is over 1 l/kg and there is good penetration into respiratory secretions, pleural fluid, the prostate, bones, and joints, but with low concentrations in the CSF. The concentrations of clindamycin in phagocytes are 10- to 20-fold (and as high as 40) times the plasma concentrations (Harari and Lincoln, 1989). Despite the high intracellular concentrations of clindamycin in phagocytes, intracellular killing is poor (Yancy et al., 1991), perhaps because the drug is sequestered in subcellular sites. Macrophages take up clindamycin by an active transport mechanism and concentrate clindamycin up to 50 times the extracellular concentration (Dhawan and Thadepalli, 1982). Because phagocytes are the cells most likely to enter infected tissues, such as abscesses, it is possible for clindamycin to be transported to an abscess to produce high concentrations in these sites (Yancy et al., 1991). Clindamycin also crosses the placental barrier, but its safety during pregnancy has not been determined for animals.

Metabolism and Excretion

Clindamycin HCl requires no metabolism to be active once administered orally. Clindamycin phosphate requires hydrolysis to occur in the plasma to be active; similarly, clindamycin palmitate requires the removal of the palmitate moiety in the small intestine to be active. The commercial form for small animals (Antirobe) is clindamycin HCl; other formulations are available for people. Elimination half-lives are shown in Table 36.9. For dogs and cats the half-life varies among studies, dose, and formulation. Generally, the half-life is long enough after administration of the oral formulation that once- or twice-daily administration is sufficient.

Clindamycin metabolites are much like those described for lincomycin. In dogs, 36% of the administered dose of clindamycin is excreted unchanged by the bile and urine. The balance of the dose appears to be active or inactive metabolites, 28% excreted by the liver in the glucuronide form (no antimicrobial activity), 28% as clindamycin sulfoxide (25% of the antimicrobial activity of the parent antibiotic), and 9% as *N*-demethyl clindamycin, which has four to eight times the antimicrobial activity of the parent compound (Dhawan and Thadepalli, 1982). The bile is the major excretion route. The presence in the colon of people administered clindamycin suppressed microbial activity for as long as 2 weeks after the discontinuation of therapy.

Adverse Effects and Precautions

Like lincomycin, the most serious adverse effect in humans is pseudomembranous colitis, from overgrowth of *Clostridium difficile*. This has not been a reported problem in animals. In dogs and cats, vomiting and diarrhea are possible but they are transient and not serious. However, gastrointestinal problems such as those discussed for lincomycin in ruminants, horses, rabbits, and rodents, are possible, and the same precautions apply that were discussed for lincomycin. Although pseudomembranous colitis from *Clostridium difficile* has not been described in animals, bacterial overgrowth and diarrhea are still possible with oral administration of clindamycin to dogs and cats.

Greene et al. (1992) reported that administration of 25 and 50 mg/kg clindamycin HCl to cats, divided in two doses, produced diarrhea and vomiting as the most common clinical signs associated with oral therapy. The highest frequency for both of these clinical signs occurred in the 50 mg/kg treatment group and was thought to be related to either a direct irritant effect on the gastrointestinal tract or some effect on intestinal water absorption. As reported for other oral drugs in cats (for example, doxycycline hyclate) oral administration of clincamycin hydrochloride has been associated with esophageal injury (Beatty et al., 2006).

A study was performed in cats to ascertain the effect of prolonged clindamycin therapy on vitamin K-dependent blood clotting times (Jacobs et al., 1989). The study showed that factor VII levels did not significantly change in cats treated with a total daily dose of 25 mg/kg orally once daily for 6 weeks compared to controls.

Clinical Use

Clindamycin possesses an antimicrobial spectrum similar to that of lincomycin, but it is much more extensively used clinically than lincomycin because of higher activity against anaerobes, increased potency, and more complete oral absorption. Clindamycin has been used to treat wounds, abscesses, osteomyelitis, and periodontal diseases caused by susceptible organisms in dogs and cats. Clindamycin is found in high concentrations in the prostate, making it an acceptable choice for treating bacterial prostatitis when caused by gram-positive organisms.

The use of clindamycin for treating toxoplasmosis is controversial. Lappin et al. (1989) performed a retrospective study of cats diagnosed with *Toxoplasma gondii* infections and found that those cats treated with clindamycin resolved all clinical signs of the disease except those lesions involving the eyes. Clindamycin alone or in combination with a corticosteroid helped to resolve the active retinochoroiditis and the anterior uveitis associated with this disease. Even though clindamycin may help clinical signs associated with toxoplasmosis, it may not help to clear organisms from the CNS or the eye. In experimentally infected cats, there was a paradoxical effect in that cats with toxoplasmosis treated with clindamycin had a worsening of clinical signs. As discussed in more detail by Davidson et al. (1996), this paradoxical effect may be due to an inhibition of intracellular killing of organisms by clindamycin.

Clindamycin has been effective in dogs with experimentally induced posttraumatic osteomyelitis caused by *Staphylococcus* spp. (Braden et al., 1987, 1988). An oral dose of 11 mg/kg twice daily for 28 days was found to be efficacious in treatment of these infected dogs, resulting in a 94% recovery rate in the clindamycin-treated dogs. Clindamycin also has been shown to be effective for treatment of superficial and deep pyoderma in dogs and is a common choice as an alternative to β-lactam antibiotics (Harvey et al., 1993; Noli and Boothe, 1999; Scott et al., 1998). Although 11 mg/kg every 24 hours has been used to treat staphylococcal infections (pyoderma) in dogs, dosing of 11 mg/kg every 12 hours is used by many veterinarians for treating most *Staphylococcus* spp. infections. Once per day at 11 mg/kg may be sufficient for bacteria with MIC values ≤ 0.5 μg/ml; twice-daily administration should be used if the bacteria have MIC values in the intermediate range of 1–2 μg/ml.

Miscellaneous Antibiotics

Bacitracin

Bacitracin is a complex labile polypeptide consisting of five to ten separate chemical components first isolated from a *Bacillus subtillus* contaminated wound in 1943 (Teske, 1984). Bacitracin A ($C_{66}H_{103}N_{17}O_{16}S$) is the major component of this mixture and accounts for most of the antibiotic activities. Bacitracin inhibits peptidoglycan synthesis in bacteria by nonspecifically blocking phosphorylase reactions, some of which occur during cell wall synthesis (Lancini and Parenti, 1982). Development of resistance to bacitracin is rare.

Bacitracin is not absorbed from the gastrointestinal tract when given orally. Systemic administration has resulted in a high incidence kidney injury (albuminuria, cylindruria, azotemia), in addition to pain, induration, and petechiae at the site of injection. In contrast, bacitracin is nonirritating and rarely induces allergic reactions when used topically. Bacitracin (bacitracin, bacitracin methylenedisalicylate, bacitracin manganese, zinc bacitracin) has been used as a feed additive in livestock, but its most common use today is in topical applications to treat susceptible skin, ear, and eye infections. Bacitracin inhibits many organisms found on skin, such as hemolytic and nonhemolytic *Streptococcus* spp., coagulase-positive *Staphylococcus* spp., and some *Clostridium* spp., and it is often combined with other antibiotics that have a gram-negative spectrum of activity (polymyxin B, neomycin). Zinc bacitracin administered topically may increase the activity of bacitracin due to zinc's astringent properties, which decrease inflammation (Harvey, 1985).

Novobiocin

Novobiocin is a dibasic acid ($pK_a = 4.3$ and 9.1) derived from coumarin and is utilized clinically as a mono- (Na^+) or dibasic- (Ca^{++}) salt form. Novobiocin possesses activity against both gram-positive and gram-negative bacteria but is more active against the gram–positive bacteria, in particular *Staphylococcus* species. Other susceptible organisms include *Neisseria* spp., *Haemophilus* spp., *Brucella* spp., and some strains of *Proteus* spp. It may be used as an alternative to penicillins in cases involving penicillin-resistant *Staphylococcus* spp., although other penicillin substitutes (cephalosporins, macrolides, clindamycin) are better clinical choices.

Novobiocin has several toxic effects on bacteria, but its exact mechanism and site of action are unknown. Novobiocin has been shown to cause nonspecific inhibition of cell wall synthesis by inhibiting formation of alternating *N*-acetylmuramic acid pentapeptide and *N*-acetylglucosamine residues; it also inhibits teichuronic acid in some species of bacteria. The concentrations needed to inhibit these cell wall components are greater than the minimal concentration needed to inhibit growth, suggesting these effects on bacteria are secondary effects. DNA and RNA synthesis, protein synthesis (β-galactosidase), respiration, and oxidative phosphorylation are also inhibited in some species of bacteria and in rat liver homogenates (Morris and Russell, 1971), with none seemingly being the primary antibiotic effect. Novobiocin is also known to induce an intracellular magnesium deficiency, but there is no direct convincing evidence that this is the mechanism responsible for novobiocin's antimicrobial activity.

Novobiocin is initially active against *Staphylococcus* spp. infections, but resistance to this antibiotic develops quickly (Morris and Russell, 1971; Harvey, 1985). Novobiocin has been combined with tetracycline to produce synergistic activity, broaden the spectrum of activity and to decrease the resistance to novobiocin, but these older combinations are used infrequently today. Novobiocin and tetracycline have been reported to be efficacious in cases of canine upper respiratory diseases such as "kennel cough" and tonsillitis (Maxey, 1980), but the use of antibiotics for this problem in dogs has declined substantially. Toxic side effects in animals and humans given novobiocin systemically have been reported and include skin rashes, leucopenia, pancytopenia, anemia, agranulocytosis, thrombocytopenia, nausea, vomiting, and diarrhea. Few side effects have been reported for this antibiotic used in its topical form in domestic animals.

Thiostrepton

Thiostrepton is a polypeptide antibiotic produced by *Streptomyces aureus* and has a predominately gram-positive spectrum, although some gram-negative organisms are also affected. Thiostrepton is not absorbed from the gastrointestinal tract and is used primarily for topical local therapy, usually combined with other antibiotics and/or glucocorticosteroids for dermatological therapy.

Rifampin (Rifampicin)

Rifampin is an antibiotic, available for many years, that has been used in people to treat tuberculosis. Equine practitioners have been familiar with rifampin for many years because of its use for treating lung infections caused by *Rhodococcus equi*. Small animal veterinarians are becoming familiar with this antibiotic because it has appeared on susceptibility reports as being active against methicillin-resistant *Staphylococcus* spp.

This antibiotic was originally discovered in the pine forests of France in the 1950s and was introduced into clinical medicine in the 1960s. It is a complex macrocyclic high-molecular-weight semisynthetic antibiotic derived from rifamycin B, produced by *Nocardia mediterrea*. Rifamycin B is chemically modified to produce rifampin. Rifampin is the United States Pharmacopeia (USP) official name, and rifampicin is the International Nonproprietary Name (INN) and British Approved Name (BAN) name; both names are synonymous. Rifamycin and rifabutin are structurally similar antibiotics – all in the group of rifamycins – but are not identical.

Mechanism of Action and Spectrum

Rifampin is a bactericidal antibiotic that acts by inhibiting bacterial RNA polymerase. Rifampin enters the microbial cell and forms stable complexes with the β subunit of DNA-dependent RNA polymerases of microorganisms. This binding results in inactive enzymes and inhibition of RNA synthesis by preventing chain initiation. This inhibition can also occur in mammalian cells, but much higher concentrations are needed. MICs for gram-positive organisms generally occur at 0.1 μg/ml, while gram negative bacteria have MIC values ranging from 8 to 32 μg/ml. This large disparity in MIC values is attributed to rifampin's ability to more easily permeate the gram-positive organism cell wall than the gram-negative organism cell wall, rather than differences in bacterial RNA polymerases. The PK/PD parameter that best predicts rifampin efficacy is the AUC/MIC ratio.

Rifampin is highly lipophilic and the intracellular penetration has made this drug valuable for treating intracellular bacteria in people and animals, including *Mycobacterium* (tuberculosis), *Staphylococcus* spp., and *Rhodococcus equi*. Rifampin has activity against gram-positive bacteria (*Staphylococcus* spp.), *Mycobacterium* spp., *Haemophilus* spp., *Neisseria* spp., and *Chlamydia* spp., but more limited activity against the gram-negative bacteria. Rifampin is active against most strains of methicillin-resistant *Staphylococcus pseudintermedius* (Perreten et al., 2010) although resistance among canine isolates has been identified (Kadlec et al., 2011).

A single mutation of the amino acid sequence of the β subunit of the DNA-dependent RNA polymerase enzyme produces resistance. Mutations result in rifampin having less affinity for the RNA polymerase enzyme. After mutations arise, clonal spread of a resistant strain may occur.

For some infections, resistance can be minimized if other antibiotics are used concurrently that will kill the mutant strains of bacteria produced in response to rifampin. The study by Berghaus et al. (2013) showed that the mutant prevention concentration (MPC) is lower when rifampin is combined with macrolide antibiotics against *Rhodococcus equi.* To reduce the rate of mutation, combination therapy with other agents has been recommended in human guidelines (Liu et al., 2011) and was the recommendation from a veterinary study for treatment of *Staphylococcus* infections in dogs (Kadlec et al., 2011). For other bacterial infections, the combination of rifampin with other antibiotics may not produce a synergistic effect (Forrest and Tamura, 2010). Whether or not combination therapy is needed for veterinary use is discussed in more detail in Section Clinical Use. There is some evidence for a synergistic effect between amphotericin B and rifampin against some fungi, particularly *Saccharomyces cerevisiae, Histoplasma capsulatum,* several species of *Aspergillus,* and *Blastomyces dermatitidis* (Medoff, 1983). However, rifampin is rarely considered for treatment of a fungal infection because other effective antifungal drugs have emerged (see Chapter 38).

Pharmacokinetics

Pharmacokinetic features of rifampin in several species are presented in Table 36.10. Rifampin is lipophilic with a large volume of distribution and good absorption in practically all animal species studied. The oral absorption is moderate to high, ranging from 38–48% in foals to 70% in adult horses (Table 36.10). In sheep the oral absorption is 16–37%. It has even been absorbed from oral and rectal administration to elephants (Egelund et al., 2015). Rifampin absorption is highest in an acidic environment, although feeding has decreased oral absorption in foals and ruminants. Rifampin is approximately 80–85% bound to plasma proteins in people and 94% in foals. Despite high protein binding, it is widely distributed to all tissues of the body, with particularly high concentrations of the drug found in the lungs, pulmonary epithelial lining fluid, liver, bile, and urine. After oral absorption or parenteral administration, rifampin is primarily metabolized to the bioactive metabolite 25-desacetyl rifampin (25-*O*-desacetyl rifampin), which is active microbiologically. There are also some minor glucuronidation products formed in the liver. Both parent and metabolite compounds are excreted in the bile. Both forms are passively filtered through the kidneys, with renal clearance being approximately 12% of total glomerular filtration rate.

Multiple dosing of rifampin often results in decreased, rather than increased, peak serum concentrations. This phenomenon is due to autoinduction of liver enzymes and is known to occur in humans, swine, dogs, calves, horses, and rodents (Frank, 1990; Berlin et al., 2017). Hepatic enzyme induction and induction of efflux mechanisms by rifampin will also alter the disposition of other drugs (discussed in more detail in Section Interactions).

The half-life ranges from 11 to 14 hours in foals and the peak concentrations vary widely (Table 36.10). The rate of excretion in the foal is lower than in the adult horse, mainly due to biliary excretion mechanisms being less developed in the foal. In dogs the half-life is approximately 8 hours, with a peak concentration of 40 μg/ml.

Interactions

Rifampin is a potent activator of a transcription factor that increases the levels of many drug metabolizing proteins, including P-glycoprotein (P-gp), and cytochrome

Table 36.10 Pharmacokinetics of rifampin/ rifampicin in animals[a]

Species	Dose (mg/kg)	Half-life (hour)	Volume of distribution (Vd) (l/kg)[b]	AUC (μg h/ml)	Peak Concentration (C_{max}) (μg/ml)	Reference

[a] Data represents a mean of the published values.

[b] Values for Vd represent Vd/F for oral doses.

[c] Concentrations measured using a microbiological assay, which can over-estimate the concentration because the metabolite is active.

[d] Data from Berlin et al., 2017; oral dose in foals was after repeated dosing for 10 days.

P-450 enzymes CYP3A, and CYP2C. The activation of occurs through an up-regulation of gene expression of intestinal and hepatic cytochrome P450 enzymes and transporters through the nuclear pregname X receptor (PXR) pathway (Reitman et al., 2011). The list of drugs identified in people that are affected by rifampin is long and summarized in other papers (Frank, 1990; Barriere et al., 1989; Lee et al., 1993; Reitman et al., 2011; Forrest and Tamura, 2010). The consequence of induction is a diminished effect of the coadministered drug and may require a higher dose or more frequent administration. When clarithromycin and rifampin were administered together in foals, it decreased the plasma drug concentration of clarithromycin by over 90% (Peters et al., 2011; Berlin et al., 2016). But in the same study, the concentration of rifampin was not affected by administration of clarithromycin. In people 4 weeks are required for full recovery of the rifampin effect after discontinuation (Reitman et al., 2011). Rifamin may have dual effects in which it can be an inhibitor of intestinal transport, as well as an inducer of other proteins.

Adverse Effects

Adverse effects have been associated with high doses and include liver injury and gastrointestinal disturbances. In a study of 344 dogs (Bajwa et al., 2013) adverse effects occurred in 16% of treated dogs. Adverse effects included vomiting, anorexia, lethargy, and weight loss. Gastrointestinal effects were the most common. There were 27% of dogs with increases in liver enzymes and this occurred between days 19 and 27 days of initiating treatment. Liver injury from rifampin is more common in dogs than in people or horses. It has been estimated that 20% or more of dogs receiving 5–10 mg/kg may develop increases in liver enzymes and some may develop hepatitis. It is advised to monitor hepatic enzymes during treatment in dogs and not to exceed a dose of 10 mg/kg per day. In the Bajwa study (Bajwa et al., 2013) cited above, a reduction in dose resolved adverse effects in many dogs. Rifampin has an unpalatable taste. It also may produce a reversible discoloration (orange–red color) to the urine, tears, and sclera. Pet owners should be warned of this possibility. Rifampin is teratogenic in laboratory animals, so its use in pregnant animals should be restricted.

Clinical Use

Susceptible organisms of interest to veterinarians include *Staphylococcus* species (including methicillin-resistant strains), *Streptococcus* spp., including *Streptococcus zooepidemicus*, *Rhodococcus equi*, *Corynebacterium pseudotuberculosis*, and most strains of *Bacteroides* spp., *Clostridium* spp., *Neisseria* spp., and *Listeria* spp. Organisms known to be resistant to rifampin are *Pseudomonas aeruginosa, E. coli, Enterobacter* spp., *Klebsiella pneumoniae*, *Proteus* spp., and *Salmonella* spp. Some gram-negative organisms may be susceptible, but it may require higher concentrations. Breakpoints for susceptibility testing of isolates from animals have not been established and the human breakpoint of ≤1, 2, and ≥4 µg/ml for susceptible, intermediate, and resistant, respectively, can be used until veterinary breakpoints are established by CLSI.

Rifampin has been used for treatment of gram-positive cocci infections in dogs (and occasionally cats), particularly methicillin-resistant *Staphylococcus* spp. that are resistant to other drugs. Rifampin has been effective for treatment of canine pyoderma caused by *Staphylococcus pseudintermedius* at a dose of 5 mg/kg once daily for 10 days (Sentürk et al., 2005).

Veterinary surgeons have recommended the addition of rifampin to treatment when biofilms are suspected to occur from surgical implants or chronic infections. Rifampin achieves high concentrations within neutrophils, endothelial cells, macrophages, and biofilms and, in people, has improved activity in combination with another antibiotic compared to that if it is used alone (Forrest and Tamura, 2010). No studies on biofilm infections have been reported in veterinary medicine.

There is a long history of rifampin use in horses. Rifampin is one of the first choices for treatment of infections in foals caused by *Rhodococcus equi* (Giguère et al., 2011). The dose for foals is typically 5 mg/kg oral, every 12 hours, but 10 mg/kg once per day also has been shown to attain effective concentrations (Berlin et al., 2017). It is routinely administered with one of the macrolide antibiotics – erythromycin, azithromycin, or clarithromycin (these drugs are discussed in Section Macrolide Antibiotics). In one uncontrolled retrospective study (Giguère et al., 2004) rifampin–clarithromycin combination was more effective than either rifampin–azithromycin or rifampin–erythromycin. In another study rifampin–azithromycin was more effective in foals than injections of tulathromycin (Rutenberg et al., 2017). Nevertheless, azithromycin is often used instead of clarithromycin because it is more convenient to administer.

Although not used frequently in ruminants, the pharmacokinetics have been studied (Table 36.10) and the recommended dose was 20 mg/kg orally once a day. The most common use in ruminants is for treatment of *Mycobacterium paratuberculosis* in cattle and sheep. It may cause remission of the infection, but does not eradicate the organism. It has also been used to treat *Mycobacterium tuberculosis* in elephants (10 mg/kg per day) (Egelund et al., 2015).

Monotherapy or combination therapy? Rifampin has been combined with other antimicrobials for treatment of *Staphylococcus* infections in dogs, and for treatment of *Rhodococcus equi* infections in foals in some protocols.

The reason for combination treatment for *Staphylococcus* infections in dogs is ostensibly to reduce emergence of resistance. However, there are no clinical studies in veterinary medicine that have demonstrated greater emergence of resistance from monotherapy with rifampin compared to combination therapy in dogs. The study by Sentürk et al. (2005) showed that monotherapy for *Staphylococcus* treatment in dogs was successful. In experimental infections rifampin monotherapy successfully eradicated staphylococci from pus in vitro and from abscesses in experimental infections (Lobo and Mandell, 1972).

The study by Kadlec et al. (Kadlec et al., 2011; Perreten et al., 2010) showed that rifampin resistance among staphylococci is infrequent. When treating staphylococcal infections in people (Falagas et al., 2007) addition of a second antibiotic did not confer additional effectiveness compared to rifampicin monotherapy for eradication of methicillin-resistant *Staphylococcus*. The study by Achermann et al. (2013) identified risk factors that contributed to resistance in staphylococcal joint infections. Rifampin monotherapy was not a statistical risk factor for development of resistance. This suggests that resistance to rifampin is possible with or without combination therapy.

The recommendation to use rifampin in combination with other antimicrobials to decrease emergence of resistance has been mainly validated in clinical situations in which long-term therapy with rifampicin was necessary (e.g., tuberculosis) and may not be the same for short-term treatment of *Staphylococcus.* Forrest and Tamura (2010) provided an extensive review of the use of rifampin in nonmycobacterial infections. They concluded that combinations of other drugs with rifampin results in indifference or antagonism and there are few examples showing synergism. For example in the treatment of staphylococcal infections, this analysis indicated that, “With a review period covering several decades, the in vitro data for rifampin combination therapy against staphylococci appear to frequently show antagonism or indifference, with synergy being found inconsistently.” This questions the benefit of adding other antibiotics to rifampin therapy for nonmycobacterial infections.

For the treatment of foals with *Rhodococcus equi* infection, rifampin has been combined with macrolide antibiotics – erythromycin, azithromycin, or clarithromycin most commonly. The recommendation of combination treatment of foals comes from consensus statements from experts (Giguère et al., 2011) and pharmacokinetic studies (Berlin et al., 2017). In pharmacokinetic studies, the concentrations in foal pulmonary epithelial lining fluid and bronchoalveolar lavage cells produced concentrations slightly lower than plasma concentrations but above the MIC_{90} for *Rhodococcus equi* (Berlin et al., 2017). It is possible that single-agent treatment is also effective, but this has not been compared with randomized, controlled studies. There is no evidence that combination treatments are synergistic using in vitro time-kill kinetic methods at achievable serum concentrations (Nordmann and Ronco, 1992), although combination with rifampin lowered the mutant prevention concentration (MPC) in vitro for some macrolides (Berghaus et al., 2012). The effects of rifampin on the pharmacokinetics of other antibiotics was discussed above in the Interactions section.

Nitrofurans

Nitrofurans comprise several synthetic compounds derived from 5-nitrofuran and possess antimicrobial activity, the 5-nitro group being required for this activity. Over 3,500 nitrofurans have been synthesized to date, with only a handful being useful in animal chemotherapy. Nitrofurans and furazolidone are banned from use in food-producing animals.

Nitrofurantoin is the main drug in this group administered orally. The mechanism of action is not well understood. After penetrating bacteria intracellular nitroreductases convert the drug to an active form through reduction of the nitro group. This action produces intermediate metabolites that bind to bacterial ribosomes and inhibit bacterial enzymes responsible for DNA and RNA synthesis.

The spectrum includes *E coli, Staphylococcus* spp., and *Enterococcus* spp. Resistance among bacteria is unusual, although *Proteus* and *Pseudomonas aeruginosa* are inherently resistant. Nitrofurans can be administered orally or topically. Oral absorption is 80% in people, but unknown in animals. Absorption is enhanced when administered with food. Serum concentrations are almost undetectable, or very low and therapeutically active concentrations are achieved only in urine. Effective concentrations cannot be achieved in the prostate or kidneys for treating upper urinary tract infection. An acid environment is required for the nitrofurans to diffuse across the cell membranes. Acidification of the urine promotes tubular reabsorption, which decreases the overall urine concentration of the drug.

Adverse Effects

The toxicology of furazolidone (*N*-5-nitro-2-furfurylidene amino-2-oxazolidinone) has been investigated extensively in laboratory, food, and companion animals as well as in humans, and has been reviewed by Ali (1989). The effects of feeding furazolidone to poultry have been reported (Ali, 1989; Mustafa et al., 1975; Czarnecki et al., 1974a, 1974b; Jankus et al., 1972).

Furazolidone has been demonstrated to be carcinogenic when used at a 0.15% w/w concentration in feed for 1 year, inducing mammary tumors in a dose-related manner. Mice fed a 0.03% w/w concentration in feed for life developed bronchial adenocarcinomas in both sexes (Ali, 1983). DNA is the principal target of furazolidone in some cells in vivo, causing cuts and mutations in DNA and binding to DNA, hence blocking the replication and transcription processes. Mutagenesis by nitrofurans in general also occurs and has been extensively reviewed by McCalla (1983), who notes several possible metabolic pathways by which nitrofurans can cause mutagenesis in mammalian cells. This potential for mutagenesis and carcinogenesis has caused the ban from use in food-producing animals.

The major disadvantage of nitrofurans to treat systemic infections is that the concentrations needed to reach the MIC also induce systemic toxicity. There are early reports in the veterinary literature on the toxicities induced when the nitrofurans are used systemically (Ali, 1983). Oral nitrofurantoin adverse effects include nausea, vomiting, and diarrhea. It turns urine rust-yellow brown color. In people, respiratory problems (pneumonitis) and peripheral neuropathy have been reported. The polyneuropathies in people are caused by a demyelination and are more common from long-term use or in patients with renal compromise. The respiratory problems have not been reported in animals, but neuropathy has been observed in dogs; the risk may be higher if there is renal insufficiency.

Clinical Use

Except for topical use, the most frequent use of nitrofurantoin in veterinary medicine is for treatment and prevention of urinary tract infections in dogs and cats that are resistant to other antimicrobials. The oral forms (Macrodantin, Furalan, Furatoin, Furadantin, and generic brands) have been administered to dogs for urinary tract infections when there are other options are limited. Although this use has been incorporated into some urinary tract infection protocols for dogs and cats, the efficacy is undetermined. Typical doses are 10 mg/kg/day divided into four daily treatments, then reduced to 1 mg/kg per day. It does not attain high enough concentrations for other infections. Although oral absorption has not been studied in dogs, in people the macrocrystalline form is slowly absorbed and less likely to cause gastric upset. The microcrystalline form is rapidly absorbed in intestine.

Although efficacy has not been examined in animals, a metaanalysis of human studies showed efficacy for short-term treatment of uncomplicated urinary tract infections (Huttner et al., 2015). Their analysis included a review of clinical trials from 1946 to 2014. They concluded that there was overall equivalence between nitrofurantoin when given for 5 or 7 days and trimethoprim–sulfamethoxazole, fluoroquinolones, and amoxicillin. Adverse effects in people were uncommon if treatment duration was kept short. The most serious adverse effects of pulmonary fibrosis and liver injury are the result of administration for several months or years.

Virginiamycin

Virginiamycin is a combination of two chemicals produced by *Streptomyces virginiae*, isolated from soil samples in Belgium in the early 1960s. Virginiamycin is classified as a peptolide antibiotic composed of the predominate M fraction ($C_{28}H_{35}N_3O_7$) and the lesser S fraction ($C_{43}H_{49}NO_{10}$) (Crawford, 1984). The optimum ratio of M : S is 4 : 1 (Gottschall et al., 1988). Administered separately, both M and S fractions have a reversible bacteriostatic action on susceptible bacterial populations; used together, their activity is synergistic, bactericidal, and approximately 100 times that found when used separately. Virginiamycin is not known to be synergistic with other classes of antibiotics. Virginiamycin is primarily active against gram-positive organisms, *Haemophilus* spp., and *Neisseria* spp., and has mild activity against the protozoan *Toxoplasma* spp. It works by inhibiting protein synthesis at the 23S ribosomal subunit, blocking translation but not transcription in susceptible bacteria. Virginiamycin is rapidly absorbed when administered orally, is excreted by the bile with no enterohepatic circulation, and has an affinity for dermal tissues (Crawford, 1984). Gottschall et al. (1988) reported that ^{14}C-virginiamycin, specifically the M fraction, was extensively metabolized in the rumen. The S fraction underwent no detectable metabolism in the rumen, and the M fraction metabolites had considerably less antimicrobial activity than the parent compound.

All virginiamycin-like antibiotics fall into one of two groups. Group A consists of polyunsaturated cyclic peptolides that have a molecular weight of approximately 500 and that contain substituted aminodecanoic acid and an oxanzole system. Group B consists of cyclic hexadepsipeptides with an approximate molecular weight of 800, and most members contain one molecule of pipecolic acid or its derivative. Both groups have low solubilities in aqueous solvents and are more soluble in organic solvents. All strongly absorb ultraviolet radiation and are therefore degraded in its presence. Virginiamycin-like antibiotics tend to affect gram-positive bacteria more than the gram negative, with *Mycobacteria* spp. being relatively resistant and *Haemophilus* spp. and *Neisseria* spp. being very sensitive. Differences in bacterial sensitivity to different virginiamycin-like antibiotics are caused by each antibiotic's particular ability to permeate that bacteria's cell wall to gain access to the ribosomes (Cocito, 1979).

Virginiamycin and virginiamycin-like antibiotics are not commonly used to treat clinical bacterial disease in domestic animals, despite their rather broad spectrum of activity. They have been used to treat swine dysentery (*Treponema hyodysenteriae*) (Olsen and Rodabaugh, 1977), but other antibiotics have proven to be more efficacious. Its main use has been as a feed additive for growth promotion in food animals such as swine (Ravindran and Kornegay, 1984; Moser et al., 1985), being approved for this use since 1975, but use of antibiotics for growth promotion is being phased out in most countries. Virginiamycin has also been studied in turkeys (Salmon and Stevens, 1990), broilers (Miles et al., 1984), and laying hens (Miles et al., 1985) as a growth promotant, all of which experienced either increased weight gain or increased egg production. The regulation and use of antibiotics used in feed for food producing animals is discussed more in other chapters (Chapters 52 and 59).

Carbadox

Carbadox (methyl 3-(2-quinoxalinylmethylene) carbazate N_1,N_4 dioxide) is a synthetic antibacterial agent primarily active against the gram-positive bacteria, although some gram-negative bacteria are affected as well. Carbadox is an antibiotic used in swine (hogs and pigs) for production purposes (e.g., increased rate of weight gain and improved feed efficiency) and therapeutic purposes (e.g., to control swine dysentery and bacterial swine enteritis). While carbadox is an antimicrobial, it does not pose the same resistance issues as other antimicrobials and is not considered important to human medicine.

Available in 1973, carbadox was marketed as a growth promotant in swine and also for the control of swine dysentery (*Treponema hyodysenteriae*), bacterial enteritis (in particular, *Salmonella cholerasuis*), and nasal infections of *Bordetella bronchiseptica* in swine (Farrington and Shively, 1979). Carbadox was shown to be better than lincomycin for the treatment of swine dysentery (Anonymous, 1980; Rainier et al., 1980). Resistance to carbadox has been reported in *E. coli* via R-plasmids (Ohmae et al., 1981). There are three approved New Animal Drug Applications (NADAs) for animal drug products containing carbadox: a premix with carbadox alone, carbadox plus pyrantel tartrate, and carbadox plus oxytetracycline.

The daily feeding of carbadox in feed concentrations of more than 100 ppm for growth promotion in pigs has resulted in toxicities in some weaned pigs, which include growth retardation, dry feces, wasting, dehydration, urine drinking, and a strong interest in salt-containing products (van der Molen et al., 1989a). It is now known that carbadox suppresses aldosterone production, leading to hypoaldosteronism, which then leads to decreased plasma sodium and increased plasma potassium concentrations. These ion alterations are due to stimulation of the renin–angiotensin system with subsequent morphological changes in the zona glomerulosa of the adrenal cortex (van der Molen et al., 1989a, 1989b, 1989c).

Regulatory actions: The United States FDA Center for Veterinary Medicine (CVM) has questions about the safety of carbadox. On April 8, 2016, the FDA announced a proposal to withdraw the approval of the drug applications for products containing carbadox. In addition, the use of antimicrobial agents for growth production in farm animals is being phased out in most countries. Regulation of food-animal antibiotics is discussed in greater detail in other chapters (Chapters 52 and 59).

Glycopeptides (Vancomycin)

Of the glycopeptides, vancomycin is the only one used in veterinary medicine. Teicoplanin has been used in Europe but is not available in the United States. Use of vancomycin in veterinary medicine is limited, but has been necessary in some cases for resistant enterococcal or staphylococcal infections. In August 20, 1997 the US Food and Drug Administration prohibited the extralabel use of glycopeptides in food-producing animals. The reason for this action is because of a fear of glycopeptide-resistant bacteria transmitted to people from treated animals (Bates et al., 1994). This action emerged from the association between resistant enterococci and the use of glycopeptides such as avoparcin and ardacin in animal feed in Europe (Bates et al., 1994). Use of these glycopeptides in animal feeds has been discontinued.

Over 80 *n*-alkyl vancomycins have been synthesized by reductive alkylation of vancomycin, with some forms being five times more active than vancomycin and with some having longer elimination half-lives (Nagarajan et al., 1989). There are new drugs related to vancomycin that have been added to human treatment, but their use of these has not been reported in animals. These drugs include dalbavancin, oritavancin, and telavancin. Telavancin (Vibativ) is a lipoglycopeptide, for once-daily administration. Dalbavancin (Dalvance) is a long-acting IV lipoglycopeptide, similar to telavancin (Vibativ). The half-life in people is 14 days, which allows for once/week treatment. Oritavancin (Orbativ) is a long-acting IV lipoglycopeptide, also similar to telavancin. The half-life is approximately 14 days, which allows for a single treatment.

Vancomycin was discovered in the 1950s. In the 1960s and 1970s it was not used much because the penicillins and cephalosporins were active against most gram-positive bacteria. But in the last 10–15 years drug-resistant enterococcal and staphylococcal infections have generated more reliance on vancomycin in human medicine. Vancomycin is a tricyclic glycopeptide having an approximate molecular weight of 1500.

It is produced by the soil-borne actinomycete *Streptomyces orientalis*. It is freely soluble in water, odorless, and slightly bitter to the taste. Vancomycin inhibits the transpeptidase and transglycosylase steps in bacterial cell-wall synthesis of gram-positive bacteria by binding to the terminal D-alanyl-D-alanine of the stem pentapeptide (cell wall precursor) of the nascent peptidoglycan. Vancomycin is bactericidal for most organisms and bacteriostatic for enterococci. The bactericidal action occurs by activating bacterial cell wall autolysins. This action occurs slowly and there is a gradual loss of cell wall integrity that may not have full effects until 24 hours. The action is time dependent, but the PK-PD that best predicts clinical results is the area-under-the-curve (AUC) to MIC ratio (AUC : MIC) with a target of > 400 considered ideal (Vandecasteele et al., 2013).

Vancomycin is highly active against gram-positive cocci (in particular, *Staphylococcus* spp. and streptococci), enterococci (*Enterococcus faecium* and *E. faecalis*), as well as *Neisseria* spp. Because it has activity against methicillin-resistant *Staphylococcus* species, including *Staphylococcus aureus* (MRSA) and *Staphylococcus pseudintermedius* (MRSP) and β-lactam resistant *Enterococcus* species, it is valuable for the treatment of these infections. It also is active against gram-positive anaerobic cocci (but not anaerobic gram-negative bacteria) and has been administered to people for diarrhea caused by *Clostridium* spp.

Adverse Effects

Toxicity studies on vancomycin have been performed in many species of laboratory animals (Wold and Turnipseed, 1981). The LD_{50} for the canine was 292 mg/kg, but death did not occur until several days after dosing. Dogs died because of kidney injury, with death due to acute nephrotoxic renal failure.

If vancomycin is administered according to the recommended dosing rates, adverse reactions described earlier are uncommon. A slow infusion is recommended to minimize histamine release. To avoid other toxic reactions, dose recommendations are designed to avoid high plasma concentrations. In people, therapeutic drug monitoring is often performed to ensure that peak concentrations are below 50 μg/ml. The current recommendations are for trough serum vancomycin concentrations of 15–20 μg/ml for intermittent dosing and plateau serum vancomycin concentrations of 20–25 μg/ml for continuous infusions. If animals have renal disease or unique physiological changes (e.g., pregnant or a neonatal animal), drug disposition may change, and peak and trough plasma concentrations should be monitored to adjust the dose appropriately.

Early formulations of vancomycin were associated with a high incidence of adverse effects. Most of these effects were associated with rapid IV administration, which induced flushing of the skin, pruritus, tachycardia, and other signs attributed to histamine release. Ototoxicity also was reported. Kidney injury risk is greater with high doses and longer exposure. Vancomycin toxicity acts as an oxidative stressor in the renal proximal tubule and can produce interstitial nephritis. The incidence of nephrotoxicity and ototoxicity may be partially caused by the common practice of simultaneously administering vancomycin with aminoglycosides. Newer and higher quality formulations of vancomycin have avoided some of the most serious adverse events, but histamine release still is possible from IV administration.

Clinical Use and Administration Guidelines

Clinical use of vancomycin has been limited in veterinary medicine and most of our clinical recommendations for use are derived from pharmacokinetic studies performed in dogs and horses and recommendations of effective blood concentrations for people. Vancomycin must be administered via IV infusion, although in rare instances intraperitoneal administration has been used. Vancomycin is poorly absorbed orally and this route is not used except to treat intestinal infections. IM administration is painful and irritating.

In dogs the half-life is somewhat shorter and the volume of distribution smaller than in humans (Zaghlol and Brown, 1988). In people, the suggested trough concentration is 15–20 μg/ml, but it is difficult to maintain these concentrations in dogs because of the short half-life. A dose rate of 15 mg/kg q 6–8 h IV actually produces peaks and troughs of approximately 40 and 5 μg/ml, respectively, but it is the most convenient dose that can be used because of the short half-life in dogs. This dose should be infused slowly over 30–60 minutes, or at a rate of approximately 10 mg/min. The total dose to be administered can be diluted in 0.9% saline or 5% dextrose solution, but not alkalinizing solutions. Vancomycin is available in vials of 500 mg to 5 g (Vancocin, other brands, and generic). If vancomycin is used to treat enterococcal infections, it is strongly recommended to coadminister an aminoglycoside (e.g., amikacin or gentamicin) because when used alone, vancomycin is not bactericidal.

Vancomycin is used infrequently in horses, but has been necessary occasionally for treatment of methicillin-resistant *Staphylococcus* infections and drug-resistant infections caused by *Enterococcus*. The guidelines for treatment were developed by Orsini et al. (2005) from their pharmacokinetic studies. A dose of 7.5 mg/kg is infused over at least 30 minutes every 8 hours in horses. Adverse reactions with this protocol have been minimal. To treat distal limb infections in horses regional limb perfusion or interosseous regional infusions have been used according to a protocol developed by Rubio-Martinez et al. (2005, 2006), in which 300 mg total dose is diluted in 60 ml saline solution and infused in the distal limb.

Methenamine

Methenamine (hexamethylenetetramine) is a urinary antiseptic most commonly used to treat urinary tract infections in small animals. It may be used in conjunction with an antibiotic or occasionally by itself in some cases of bacterial urinary tract infections that have become refractory to conventional antibiotic therapies. Methenamine is activated by a hydrolysis reaction to form formaldehyde and ammonia in acidic urine. It may be effective against a wide variety of gram-positive and gram-negative organisms. It can be either bacteriostatic or bactericidal depending on the pH of the urine (Harvey, 1985).

Methenamine is quickly absorbed when given orally, but absorption is not complete because some is hydrolyzed in the stomach. It is excreted via the urine, and is associated with a low systemic toxicity.

The urine must be at an acidic pH in order to liberate free formaldehyde; therefore, methenamine is most effective when the urine pH is 6 or below. One of the forms of methenamine used is methenamine hippurate, which is available in human tablet form and is administered to dogs at a dose extrapolated from people of 500 mg per dog, oral, every 12 hours. Another form, methenamine mandelate is no longer available commercially. Methenamine has also been administered with urinary acidifiers to lower the urine pH. Concurrent use of other urinary acidifiers, ascorbic acid, arginine HCl, methionine, cranberry juice, and ammonium chloride, may enhance the antibacterial action of methenamine because acidic urine also exerts some independent weak antibacterial activity. Sulfonamides should not be administered with methenamine due to the formation of insoluble formaldehyde–sulfonamide precipitates. Since methenamine is largely eliminated via the kidney, its use should be restricted or closely monitored in cases of renal insufficiency (Harvey, 1985). Methenamine is less effective for treating infections caused by urea-splitting organisms, which increase the urine pH (e.g., *Proteus mirabilis*).

Methenamine mandelate has been used experimentally in the treatment of burn wounds in rats. Topical doses of 5% and 10% were highly efficacious against experimentally induced burns infected with a virulent strain of *Pseudomonas* spp. (Taylor et al., 1970).

Polymyxins

Polymyxins are a group of *N*-monoacetylated decapeptides discovered in 1947 and are produced by *Bacillus polymyxa*. They contain seven amino acids in a cyclic configuration and have a molecular weight of approximately 1000. Several polymyxins have been isolated and have been named A, B, C, D, E, and M. Of these six antibiotics, B and E in their sulfate salt forms are the only ones used clinically. Polymyxin B1 has a pK_a ranging from 8 to 9. The largest use of polymyxin has been in topical ointment preparations. Polymyxin B sulfate is a mixture of polymyxin B1 ($C_{56}H_{98}N_{16}O_3$) and polymyxin B2 ($C_{55}H_{96}N_{16}O_{13}$); polymyxin E is more commonly known as colistin (Harvey, 1985). Colistin has seen a resurgence for treatment of carbapenem-resistant Enterobacteriaceae (CRE) in people for which few other treatment options exist. This use has not been examined in veterinary medicine.

Polymyxins are basic surface-active cationic detergents that interact with the phospholipid within the cell membrane, penetrate that membrane, and then disrupt its structure. This action subsequently induces permeability changes within the cell that result in cell death, giving polymyxins bactericidal properties.

Polymyxins are not absorbed to any extent from the gastrointestinal tract when administered orally. Administration is by injection, usually IV. After administration polymyxin B is 70–90% plasma protein binding and distributed to the heart, lungs, liver, kidney, and skeletal muscle, with excretion mainly via the urine (Sande and Mandell, 1990a). The pharmacokinetics of some of the polymyxins in calves, ewes, rabbits, and dogs is reviewed in greater detail elsewhere (Ziv and Sulman, 1973a; Ziv et al., 1982; Craig and Kunin, 1973; al-Khayyat and Aronson, 1973a, 1973b). Ziv and Sulman (1973a) reported that an IV administration of 5 mg/kg polymyxin B in ewes resulted in a serum half-life of 2.7–4.3 hours and a Vd of 1.29 l/kg.

Polymyxins have a gram-negative antibacterial spectrum, which includes species of *Aerobacter, Escherichia, Histophilus, Klebsiella, Pasteurella, Pseudomonas, Salmonella,* and *Shigella. Proteus* spp. and most strains of *Serratia* spp. are not affected by polymyxins, and all gram-positive bacteria are resistant. If bacteria are sensitive to the polymyxins, they rarely acquire resistance.

Since the polymyxins are not absorbed into the body when given orally, polymyxin B has been used for “bowel sterilization” prior to abdominal surgeries and in irrigation solutions to flush the peritoneal cavities during those procedures. Polymyxins used to be the major drugs for treatment of *Pseudomonas* infections in humans, but since the advent of better penicillins, aminoglycosides, and cephalosporins, their use has declined over time. Nephrotoxicity occurs due to glomerulus and tubular epithelium damage. In addition, respiratory paralysis (usually caused by a rapid IV injection, too much peritoneal lavage, or a preexisting renal condition) and CNS dysfunction, including depression, pyrexia, and anorexia, also occur.

Polymyxins are mainly used in topical skin, mucous membrane, eye, and ear preparations. One of the most common “first-aid” antibiotics is the *Triple Antibiotic* containing bacitracin zinc, neomycin sulfate, and polymyxin B sulfate. Typically, one gram of ointment contains 400 units bacitracin zinc, 3.5 mg neomycin sulfate, and 5,000 units polymyxin B sulfate 5,000. No adverse systemic effects have been reported when they are applied to intact or denuded skin surfaces. Polymyxin antibacterial activity is markedly decreased in the presence of pus, in tissues containing acidic phospholipids, divalent cations, unsaturated fatty acids, debris, purulent exudate, quaternary ammonium compounds, and in the presence of anionic detergents or other chemicals that antagonize cationic detergents (Harvey, 1985).

In addition to its narrow-spectrum antimicrobial properties, polymyxin B has demonstrated a protective effect against the adverse effects of endotoxin produced by gram-negative bacteria. Polymyxin is capable of acting as a chelating agent to bind the lipid A portion of endotoxin in a 1 : 1 ratio to neutralize lipopolysaccharide. This effectively renders the endotoxin inactive, thereby preventing most of the adverse effects of gram-negative endotoxin. This property has been studied more in horses than in other species and has been part of an antiendotoxin protocol in equine medicine (Morresey and Mackay, 2006). Infusions ranging from 1,000 to 10,000 units per kg (a common dose is 6,000 units/kg, equivalent to 1 mg/kg) administered every 8 hours have been shown to be safe and effective for treating endotoxemia in horses.

Polymyxin B is available in vials containing 500,000 polymyxin B units. In some dosage protocols, the dose is listed in milligrams instead of units. One milligram of polymyxin B base is equivalent to 10,000 units of polymyxin B, and each microgram of pure polymyxin B base is equivalent to 10 units of polymyxin B.

Spectinomycin

Spectinomycin (Spectam) resembles aminoglycosides in some properties. It is highly water soluble and is easily mixed in aqueous solutions. Compared to aminoglycosides, it does not contain amino sugars or glycosidic bonds, but it has an aminocyclitol nucleus like the aminoglycosides. An important difference between spectinomycin and the aminoglycosides is in the adverse effects and spectrum of activity. Spectinomycin lacks the toxic effects of aminoglycoside antibiotics and can be used without concerns about kidney injury. Most formulations of spectinomycin have been removed from the commercial market. The combination products for livestock (for example, lincymycin–spectinomycin) have been discontinued in some countries.

Antimicrobial Activity

Spectinomycin, like aminoglycosides inhibits protein synthesis via a 30S ribosomal target. It is a broad-spectrum drug with activity against gram-positive and some gram-negative bacteria, but little anaerobic activity. It also has good activity against *Mycoplasma*. It is used in cattle because it has activity against *Mannheimia (Pasteurella) haemolytica, Pasteurella multocida,* and *Histophilus somni* (formerly *Haemohilus somnus).*

Pharmacokinetics

Like the aminoglycosides, spectinomycin has a small volume of distribution. It is poorly absorbed after oral administration (10% or less), but some systemic levels are achieved after oral administration in monogastric animals. Most of an oral dose is eliminated in the feces, but after an injection the primary route of elimination is the kidneys. Oral administration has been used for a local effect for treatment of diarrhea.

The half-life of spectinomycin is approximately 2 hours in cattle at a dose of 10 mg/kg IM or IV, and 1.2 hours after a dose of 20 mg/kg IV. After oral dosing in dogs of 100 or 500 mg/kg, the plasma concentrations (peak) were 22 and 80 µg/ml, respectively. The half-life in dogs is 2.72 hours at the 100 mg/kg dose. After IM injection in dogs, the half-life was 1.1 hours. In pigs, the half-life was 1 hour after IM administration.

Clinical Use

Older formulations have been used that contain both lincomycin and spectinomycin. Formulations containing only spectinomycin (Spectam) include spectinomycin oral solution, spectinomycin powder for drinking water, and spectinomycin hydrochloride injection for poultry. Spectinomycin sulfate has been used for injection in cattle (Adspec®), which is more highly absorbed than the hydrochloride salt. Spectinomycin tablets for dogs are an old formulation that is not currently used. (The sponsor of Adspec®, Zoetis, has announced discontinuation of the manufacture of this drug.) There are no small animal formulations currently available but the old formulation for small animals was spectinomycin hydrochloride pentahydrate administered as tablets (22 mg/kg twice daily) or by injection (5–10 mg/kg) for treatment of nonspecific infections.

Clinical use is primarily confined to food animals. Administration to horses has not been reported. In pigs, spectinomycin has been used orally as spectinomycin hydrochloride oral solution. It has in vitro activity against some gram-negative bacteria and has been used as a feed additive for pigs because of its activity against *Mycoplasma*. It has also been administered orally to pigs for treatment of bacterial enteritis caused by *E. coli* (50–100 mg/animal, oral) and as an injection for treatment of respiratory infections. In poultry, spectinomycin has been used as injection and added to drinking water for prevention and treatment of respiratory disease and other infections.

In cattle, spectinomycin has been used as an IM injection for treatment of respiratory infections (10–15 mg/kg SC in the neck, q 24 h × 3–5 days). Poultry formulations were used in cattle off-label prior to approval of Adspec®, when it was a past practice to mix the water soluble powder intended for drinking water as an IV solution for administration to cattle. This use is discouraged because it may result in severe pulmonary edema and death.

Oxazolidinones

The oxazolidinones are infrequently used in veterinary medicine. The most common one used from this class is linezolid (Zyvox®), which was the first one introduced to human medicine. It is valuable for use in people to treat resistant gram-positive infections caused by enterococci and methicillin-resistant *Staphylococcus* spp. Because there are so few drugs active against methicillin-resistant *Staphylococcus* (MRSA), it is the only oral drug that is consistently effective for this infection in people and also used for drug-resistant *Enterococcus*. Because of the increase in the incidence of methicillin-resistant *Staphylococcus* in dogs and cats (methicillin-resistant *Staphylococcus pseudintermedius,* MRSP), the use of linezolid has been increasing in these animals. The brand name of this drug (Zyvox®) was almost prohibitively expensive, but the newer generic forms are one-tenth of the cost, or less, which has increased the use. There is a new oxazolidinone available for people, tedizolid (Sivextro®) which is available in tablets (200 mg) and IV. It has properties similar to linezolid and clinical uses similar in people.

Linezolid inhibits protein synthesis by binding to the bacterial ribosome. It is bacteriostatic by binding to a site on the bacterial 23S ribosomal RNA of the 50S subunit. This prevents formation of the 70S ribosomal unit, and therefore protein synthesis is inhibited. It has activity primarily against gram-positive bacteria, particularly staphylococci and enterococci. Linezolid has good penetration into cells and extracellular fluid. Urine concentrations are high enough to inhibit urinary tract pathogens. In dogs the pharmacokinetics are similar to humans. The oral absorption is almost 100%, with or without food, and the half-life is slightly faster than humans. Linezolid does not undergo hepatic P450 metabolism, and one-third of the total clearance relies on the kidneys.

Adverse effects

Adverse effects have not been reported from use in dogs or cats, but clinical use has been rare enough that this may not be detected. In people, nausea and diarrhea can occur. Long-term use can cause bone marrow suppression (e.g., thrombocytopenia) in people, but this has not been reported in dogs or cats. Rarely, anemia and leukopenia have been observed in people. The risk of bone marrow suppression is most evident after 2 weeks of treatment. Long treatment courses in animals should be accompanied by periodic CBC measurements until the risk of bone marrow suppression is better understood in these animals.

Drug Interactions

Linezolid is a Type-A monoamine oxidase inhibitor (MAOI). Possible interactions occur with serotonin reuptake inhibitors such as fluoxetine and selegiline to produce serotonin syndrome. Interactions are also possible if administered with adrenergic drugs such as phenylpropanolamine. However, this effect has not been reported for animals. Linezolid is not expected to affect metabolism of other drugs. Rifampin may decrease plasma concentrations. Intravenous formulation is physically incompatible with other drugs in IV line. If administered with other drugs IV, flush out the administration line first.

Clinical Use

The use of linezolid should be selected on the basis of susceptibility monitoring and it is not recommended for routine use in animals unless other options are not available because of drug resistance. CLSI lists the break point for susceptibility as less than or equal to 4.0 μg/ml for *Staphylococcus* spp. and less than or equal to 2.0 μg/ml for *Enterococcus*. Linezolid is available in 400- and 600-mg tablets, 20-mg/ml oral suspension powder, and 2-mg/ml injection. The tablets have been expensive, but recent introduction of generic forms has lowered this cost. A typical dose for dogs and cats is 10 mg/kg q 12 h oral or IV.

Fluoroquinolone Antimicrobial Drugs

Mark G. Papich

The fluoroquinolone antibacterial agents are among the most important antimicrobials used in veterinary medicine. They are used in practically all species and have a broad spectrum of activity that includes most of the important veterinary bacterial pathogens. Since their first introduction in the late 1980s (discussed in previous editions of this book), the use of fluoroquinolones has expanded tremendously.

The fluoroquinolones are synthetic antibacterial agents introduced in veterinary medicine first as enrofloxacin. Since then, there has been a great deal of research on this class of drugs to better understand their mechanism of action, antimicrobial spectrum, pharmacokinetics in a wide variety of animal species, and clinical uses. In addition, pharmaceutical companies have developed new agents in this class to increase the number of drug choices available to veterinarians. The advantages of the fluoroquinolones are that they are rapidly bactericidal against a wide variety of clinically important bacterial organisms, are potent, are well tolerated by animals, and have been administered via a variety of routes (orally via tablets and drinking water, subcutaneously, intravenously, intramuscularly, and topically).

Fluoroquinolones approved for use in veterinary medicine for small animals are shown in Table 37.1. Fluoroquinolones that are approved for humans and are of potential interest for veterinary medicine include ciprofloxacin. The newest generation of fluoroquinolones, with increased activity against gram-positive cocci and anaerobic bacteria, includes levofloxacin, moxifloxacin, gatifloxacin, and the veterinary drug pradofloxacin.

Chemical Features

The currently available fluoroquinolones have the same quinolone structure (Figure 37.1). The addition of the fluorine group at position 6 gives these the characteristics of a fluoroquinolone, and various other chemical substitutions and side groups account for the different physical characteristics of each drug. Enrofloxacin has one fluorine substitution, difloxacin has two fluorine substitutions, and orbifloxacin has a three-fluorine substitution, but the presence of more than one fluorine does not increase antibacterial effects (Asuquo and Piddock, 1993). When lipid solubility is expressed as the octanol: water partition coefficient, enrofloxacin has among the highest lipophilicity. By comparison, ciprofloxacin has a partition coefficient that is approximately 100-fold less than that of enrofloxacin; the corresponding partition coefficients of orbifloxacin and marbofloxacin are slightly higher than that of ciprofloxacin (Asuquo and Piddock, 1993; Takács-Novák et al., 1992). But there are no studies available to show that these chemical differences among the drugs can account for differences in clinical response. However, chemical differences may account for some variation in absorption and distribution. For example, ciprofloxacin oral absorption is approximately one-half that of enrofloxacin in dogs; ciprofloxacin absorption in horses is less than 10%, compared to 60% for enrofloxacin. The less lipid-soluble fluoroquinolones (marbofloxacin, orbifloxacin) have a lower volume of distribution (Vd) than the ones with higher lipid solubility (enrofloxacin) (Table 37.2). One explanation for this observation is that the more lipid-soluble drugs have higher intracellular concentrations, but higher tissue binding also could explain the differences in volume of distribution.

The most important structural difference in recent years is the addition of a substitution at position 8. These are usually referred to as *third-generation* fluoroquinolones to distinguish them from the *second-generation* drugs such as ciprofloxacin and enrofloxacin. For some human drugs, the addition is a methoxy (moxifloxacin), and for one of the veterinary drugs, it is a cyano group at position 8 that confers increased spectrum of activity.

Quinolones are amphoteric molecules that can be protonated at the carboxyl and the tertiary amine portion of the molecule (Martinez et al., 2006). The pK_a varies

Table 37.1 Examples of fluoroquinolones used in veterinary medicine

Drug	Brand name(s)	Approved species
Enrofloxacin	Baytril, and generic	Dogs, Cats, Cattle, Pigs
Danofloxacin	Advocin	Cattle
Orbifloxacin	Orbax	Dogs, Cats
Pradofloxacin	Veraflox	Cats, (also dogs in some countries)
Marbofloxacin	Zeniquin, Marbocyl	Dogs, Cats (other species outside the U.S.)
Ciprofloxacin	Cipro and generic	Not approved for animals; human drug
Ibafloxacin	Ibaflin	No longer available (formerly dogs, cats)
Difloxacin	Dicural	No longer marketed (formerly dogs, and in some countries, cattle, and poultry)

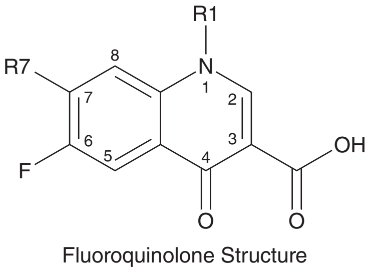

Figure 37.1 Structure of the fluoroquinolones. Features necessary for antibacterial activity are fluorine at position 6, ketone at position 4, and carboxyl at position 3. (Figure 37.2 shows other additions.) Addition of cyclopropyl, ethyl, or fluorophenyl at position 1 and of piperazine at position 7 increases the spectrum of antibacterial activity. Substitutions at position 8 broaden the spectrum of activity.

among the drugs slightly, but generally the pK_a for the carboxyl group is 6.0–6.4 (5.5–6.3 in some references) and the pK_a for the nitrogen of the piperazine group is 7.5–8 (Nikaido and Thanassi, 1993) (as high as 7.6–9.3 in some references). For two common drugs, enrofloxacin and ciprofloxacin, the pK_a for the carboxyl group is 6.0 and 6.1, respectively, and 8.8 and 8.7 for the amine, respectively (Martinez et al., 2006). The isoelectric point is midway between the pK_a for each ionizable group. Therefore, at physiological pH fluoroquinolones exist as zwitterions, in which both of the respective anionic and cationic groups are charged. It is at the isoelectric point (near the physiological pH) that fluoroquinolones are the most lipophilic and capable of diffusing across lipid membranes (Takács-Novák et al., 1992; Martinez et al., 2006).

Structure–Activity Relationships

Figure 37.1 shows the basic quinolone structure. The carboxyl group at position 3 and the ketone at position 4 are necessary for the antibacterial activity. The fluorine at position 6 differentiates the quinolones from the fluoroquinolones and accounts for the improved gram-negative and gram-positive activity over the nonfluorinated quinolones, increased potency, and increased entry into bacteria. At position 1, addition of a cyclopropyl (as for enrofloxacin and ciprofloxacin in Figure 37.2), an ethyl or a fluorophenyl improve the spectrum of activity against gram-positive and gram-negative bacteria. Addition of a piperazine at position 7, as demonstrated for ciprofloxacin, marbofloxacin, and enrofloxacin (Figure 37.2), improves the spectrum of activity to include pseudomonads, among other gram-negative bacteria. The change from a nitrogen (nalidixic acid) to a carbon at position 8 decreased some of the adverse central nervous system effects and increased activity against staphylococci.

Table 37.2 Interpretive categories for susceptibility break points (CLSI, 2015)

Drug	Species	Susceptible (μg/ml)	Intermediate (μg/ml)	Resistant (μg/ml)
Enrofloxacin	Dogs, cats	≤0.5	1–2	≥ 4
Orbifloxacin	Dogs, cats	≤1.0	2–4	≥ 8
Ciprofloxacin*	People	≤1.0	2	≥ 4
Marbofloxacin	Dogs, cats	≤1.0	2	≥ 4
Enrofloxacin	Pigs (gram negative)	≤0.25	0.5	≥ 1
Enrofloxacin	Pigs (gram positive)	≤0.5	1	≥ 2
Enrofloxacin	Horses	≤0.25	0.5	≥ 0.5
Enrofloxacin	Cattle (BRD)	≤0.25	0.5–1	≥ 2
Pradofloxacin	Dogs, Cats	≤0.25	0.5–1	≥ 2
Danofloxacin	Cattle (BRD)	≤0.25	0.5	≥ 1

* The breakpoint listed for ciprofloxacin is based on human use, not veterinary use.

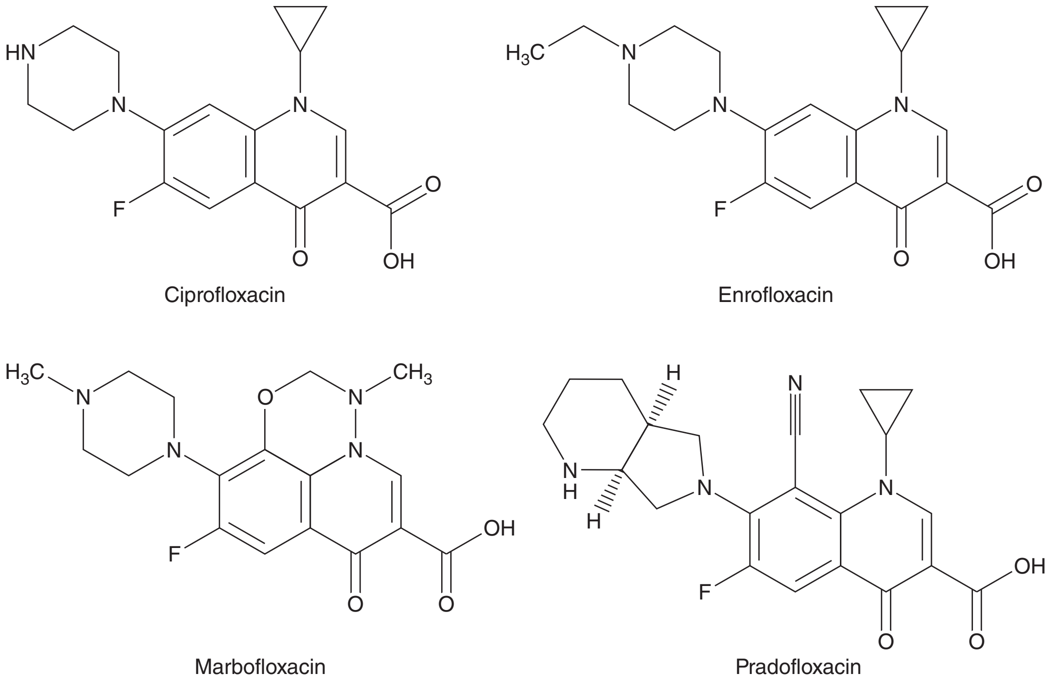

Figure 37.2 Structure of the fluoroquinolones. These representative structures show modifications from the basic structure presented in Figure 32.1. Features necessary for antibacterial activity are fluorine at position 6, ketone at position 4, and carboxyl at position 3. Addition of cyclopropyl, ethyl, or fluorophenyl at position 1 and of piperazine at position 7 increases the spectrum of antibacterial activity.

The *third-generation* fluoroquinolones have a bicyclic substitution at position 7, instead of a piperazine. This increased the activity to include a wider range of bacteria. In addition, a substitution at the 8 position on the ring enhances the bactericidal effects and improves the spectrum of activity to include more gram-positive and anaerobic bacteria. For example, the 8-methoxy substitution produces the drug moxifloxacin, a human quinolone with improved activity against gram-positive bacteria (Behra-Miellet et al., 2002; Aktaç et al., 2002; Pestova et al., 2000). Pradofloxacin, a veterinary quinolone with similar activity has a cyano substitution at position 8, which improves the activity against gram-positive and anaerobic activity compared to enrofloxacin and ciprofloxacin (Silley et al., 2007). This drug is discussed in more detail in Section Pradofloxacin Use in Dogs and Cats. A comparison of the activities of the veterinary fluoroquinolones against gram-positive and gram-negative bacteria can be illustrated in Figure 37.3 (using data from Wetzstein, 2005).

Mechanism of Action

Quinolones are bactericidal by inhibiting bacterial DNA replication and transcription. Two-stranded DNA is tightly coiled in the cell and must be separated for transcription and translation. To facilitate coiling, winding, and unwinding, the enzyme DNA gyrase allows the strands to be cut and reconnected. This allows coiling because negative supercoils can be introduced. DNA gyrase, a topoisomerase, consists of A and B subunits. The most common target site for quinolones is the A subunit of DNA gyrase coded by the gene *gyrA*. Mammals are resistant to the killing effects of quinolone antimicrobials because topoisomerase II in mammalian cells is not inhibited until the drug concentration reaches 100–1000 μg/ml. Bacteria are inhibited by concentrations of 0.1–10 μg/ml or less. Concentrations achieved in animals and people are much lower as seen by the Clinical Laboratory Standards Institute (CLSI, 2015) breakpoints (Table 37.2). Another target is the topoisomerase IV enzyme composed of subunits *parC* and *parE*. This site of action is less important for gram-negative bacteria but is a target of fluoroquinolones in some gram-positive bacteria such as streptococci and staphylococci (Ferrero et al., 1995). Among the newer generation fluoroquinolones – for example the veterinary drug pradofloxacin, and the human drugs moxifloxacin and gatifloxacin – the primary target for gram-positive bacteria may be the DNA-gyrase rather than topoisomerase IV, or these drugs also may be dual inhibitors against both targets (Intorre et al., 2007). Therefore, older fluoroquinolones have high activity against DNA-gyrase in gram-negative bacteria, but less against the topoisomerase IV of gram-positive bacteria. But the broader activity of newer fluoroquinolones can be attributed to higher affinity for both the DNA-gyrase in gram-negative and gram-positive bacteria,

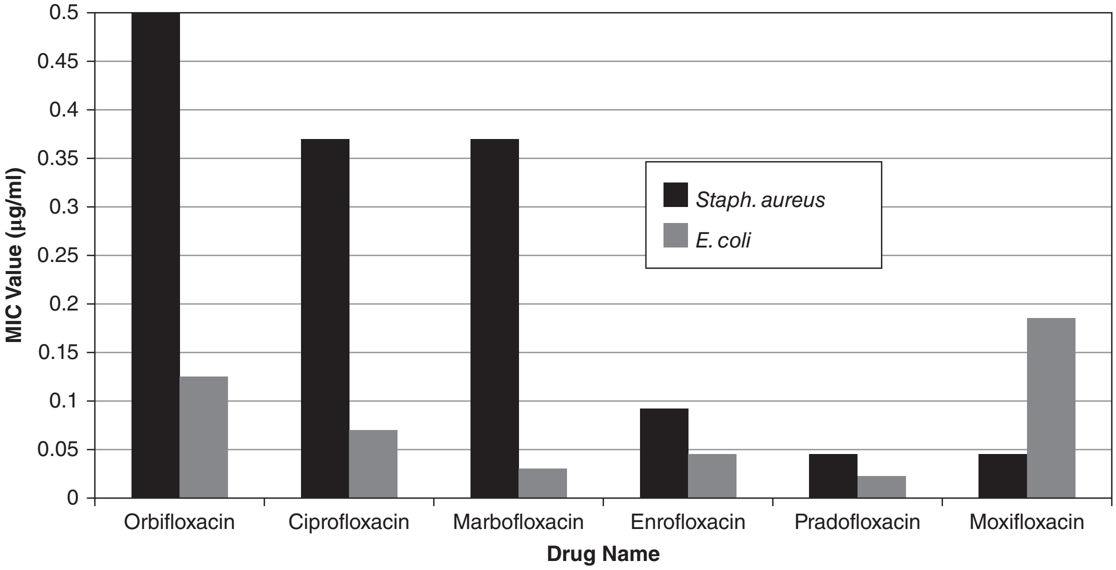

Figure 37.3 Comparison of fluoroquinolone MIC values for veterinary drugs, and compared to two human drugs, moxifloxacin and ciprofloxacin. Source: Data from Wetzstein, 2005.

as well as activity for the topoisomerase IV of gram-positive bacteria (Drlica and Zhao, 1997; Blondeau et al., 2004).

Antibacterial Spectrum

Fluoroquinolones in general exhibit good activity against most gram-negative bacteria, especially those of the Enterobacteriaceae. Representative minimum inhibitory concentration (MIC) values are shown in Table 37.3. *Escherichia coli, Klebsiella* spp., *Proteus* spp., *Salmonella* spp., and *Enterobacter* spp. are usually susceptible. *Pseudomonas aeruginosa* is variably susceptible and, when it is susceptible, usually has a higher MIC than other susceptible organisms. Against *P. aeruginosa,* ciprofloxacin is the most active (Rubin et al., 2008). Other bacteria susceptible to fluoroquinolones include intracellular organisms (*Rickettsia* spp., *Chlamydia,* and *Mycobacterium* spp.) and *Mycoplasma* spp.

Gram-positive bacteria are variably susceptible. *Staphylococcus aureus, Staphylococcus pseudintermedius,* and other *Staphylococcus* species usually are susceptible. However, the MIC values for staphylococci typically are higher than for gram-negative bacteria, and staphylococcal resistance to fluoroquinolones can be common.

In general, ciprofloxacin is more active than enrofloxacin against gram-negative bacilli, and enrofloxacin is more active against *Staphylococcus* species (Grobbel et al., 2007; Blondeau et al., 2012). Marbofloxacin activity usually falls between enrofloxacin and ciprofloxacin. The newer fluoroquinolones, such as moxifloxacin, gatifloxacin, and the veterinary drug pradofloxacin, have increased activity against gram-positive cocci and anaerobic bacteria (Behra-Miellet et al., 2002; Aktaç et al., 2002; Pestova et al., 2000; Silley, 2007) (Figure 37.3).

Factors that may affect activity are cations at the site of infection and low pH. Cations such as Al^{+3}, Mg^{+3}, Fe^{+2},

Table 37.3 Comparative microbiological data for common pathogens. Sources: Pirro et al., 1997, 1999; Asuquo and Piddock, 1993; Stegemann et al., 1996; Spreng et al., 1995; pradofloxacin FOI summary, and manufacturer data.

	MIC of bacteria (µg/ml)			
Drug	***Pasteurella multocida***	***Escherichia coli***	***Staphylococcus pseudintermedius***	***Pseudomonas aeruginosa***
Ciprofloxacin	0.015	0.03	0.25	0.5
Difloxacin	<0.05	0.11–0.23	0.25–0.91	0.92
Enrofloxacin	0.03	0.03–0.06	0.125	2.0
Marbofloxacin	0.04	0.125–0.25	0.23–0.25	0.94
Orbifloxacin	0.05	0.125–0.39	0.25–0.39	6.25–12.5
Pradofloxacin	0.008	0.03	0.06	

MIC values listed are MIC_{90} and represent an average from available published literature or manufacturer technical information.

and Ca^{+2} can bind a carboxyl group on the drug and significantly decrease activity. Low pH at the site of action also can affect the MIC (Ross and Riley, 1994), especially for drugs that have a piperazine at position 7 (Figures 37.1 and 37.2). For example, in urine, the MIC for fluoroquinolones may increase due to the presence of cations in the urine and low pH (Fernandes, 1988). This activity in urine may increase the MIC from fourfold to 64-fold. Fluoroquinolone activity in an abscess is not diminished despite the observation that in pus there is cellular material that can bind drugs, a low pH, and slow-growing bacteria (Bryant and Mazza, 1989). The presence of a foreign body, albumin, globulin, pus, anaerobic conditions, and dead bacteria did not affect the activity of fluoroquinolones (Rubinstein et al., 2000). The activity of fluoroquinolones in this milieu may explain its efficacy for treating infections associated with abscessation.

Susceptibility Testing

Susceptibility testing is performed either by the agar-disk-diffusion (ADD) method or broth dilutions (MIC test). The CLSI (CLSI, 2015) has published interpretive categories for breakpoints for most fluoroquinolones (Table 37.2). For isolates in the "intermediate" range, this is a category that implies that an infection due to the isolate may be appropriately treated in body sites where the drugs are physiologically concentrated or when a high dosage of drug can be used. Therefore, the dose can be increased in these instances, or successful treatment might be possible of the drug is applied topically or for a urinary tract infection. The MIC quality control ranges for wild-type organisms are also available from CLSI.

Resistance

There are multiple resistance mechanisms that have been identified for fluoroquinolones. These include: decreased drug permeability, increased drug efflux (efflux pumps), gyrase protecting enzymes, altered targets, and plasmid-mediated resistance. Of all the mechanisms listed, resistance most frequently develops via the *gyrA* mutation that codes for the A subunit of the DNA gyrase enzyme. A mutation at the serine-83 residue has been one of the most common, but at least 10 additional mutations at the *gyrA* gene have been identified to confer resistance (Ferrero et al., 1995). A mutation in the *parC* gene that codes for topoisomerase IV enzyme also is important (*grlA* mutation in staphylococci). A mutation in *parC* coding for resistant topoisomerase IV causes resistance when detected with mutations of *gyrA*, thus presence of both mutations usually produces high-level resistance. The multidrug resistance membrane efflux mechanisms reduce the accumulation of antibiotics in the bacteria. These efflux mechanisms are known to produce a high-level resistance to fluoroquinolones when they are present with other target site mutations (Zhanel et al., 2004). Because the efflux membrane pumps may affect other drugs, this may produce cross-resistance to other antimicrobials. Generally, there is cross-resistance among the fluoroquinolones. That is, although MIC values among susceptible strains can vary by a few dilutions, a fully resistant strain will typically be resistant to all the fluoroquinolones.

Resistance can occur through a multistep process (Everett et al., 1996). A single mutation can increase the MIC slightly (perhaps one dilution), and each subsequent mutation produces a progressively higher level resistance in a stepwise fashion. Unlike plasmid-mediated bacterial resistance, in which resistance may disappear after selective antibiotic pressure is removed, chromosomal (mutational) resistance exhibited by fluoroquinolone-resistant bacteria can be maintained in bacteria after drug administration is discontinued. Plasmid-mediated resistance has been found in *E. coli* and *Klebsiella* organisms, but the clinical significance of plasmid-mediated resistance has not been identified (Martinez-Martinez et al., 1998).

Clinical Resistance Problems

Resistance to fluoroquinolones has become a problem in human medicine and some investigators have attributed this to over-prescribing of these drugs. Resistance to fluoroquinolones by *E. coli, Staphylococcus aureus,* and *Streptococcus pneumoniae* has been well documented (Chen et al., 1999; Murphy et al., 1997; Sanders et al., 1995; Neu, 1992; Peña et al., 1995; Perea et al., 1999; Everett et al., 1996). Clinical resistance in human hospitals among staphylococci appeared relatively quickly after introduction of ciprofloxacin (Neu, 1992; Sanders et al., 1995; Hedin and Hambreus, 1991).

Resistant bacteria also have been identified in practically all animal species. Resistance in small animals has been documented for *E. coli, P. aeruginosa, Enterobacter, Proteus,* and other gram-negative bacteria. Resistance among staphylococci isolated from small animals has also been documented, particularly with methicillin-resistant *Staphylococcus pseudintermedius* (MRSP) (Couto et al., 2014; Bemis et al., 2009; Jones et al., 2007; Cole et al., 1998). The acquisition of specific *gryA/grlA* genes associated with phenotypic resistance to fluoroquinolones is strongly correlated with multidrug resistant methicillin-resistant *Staphylococcus pseudintermedius* (MRSP) (McCarthy et al., 2015).

Pseudomonas organisms have been particularly troublesome because single-step mutations are common for this bacteria, which can easily progress to high-level resistance. This is an important problem in companion animal medicine because, except for the fluoroquinolones, there are no other oral drugs with which to treat infections caused by *Pseudomonas aeruginosa.* Factors leading to resistant *P. aeruginosa* are an inadequate dosage and extended treatment at low doses. Various studies have confirmed increased frequency of resistance among *Pseudomonas aeruginosa* isolated from chronic infections in dogs (Petersen et al., 2002; Martin Barrasa et al., 2000; Cole et al., 1998).

Human Health Risks from Drug Resistant Bacteria

Infectious disease experts have warned that administration of fluoroquinolones to animals may be a public health concern. Transfer of fluoroquinolone resistance from animals to people has been suggested to occur for *Campylobacter* species (Endtz et al., 1991) and *Salmonella typhimurium* type DT-104 (Threlfall et al., 1995, 1997; Griggs et al., 1994). An increase in the incidence of resistant *Campylobacter jejuni* infecting people was linked to consumption of *Campylobacter*-contaminated chicken. The increased resistance occurred primarily after 1995, which coincides with the time that fluoroquinolones were approved for use in poultry as an additive to drinking water (Smith et al., 1999). Investigators have also associated resistance in salmonellae with veterinary use of fluoroquinolones in livestock (Piddock et al., 1998). However, resistant strains of *Salmonella typhimurium* may have occurred spontaneously because some of the resistant salmonellae have come from farms in which fluoroquinolones were not administered to animals (Griggs et al., 1994). Nevertheless, some scientists have warned that use of fluoroquinolones in livestock is a public health risk because it can potentially lead to resistant mutants of salmonellae being passed on to humans through the food chain. Because of these concerns, there have been limited approvals of fluoroquinolones for food-producing animals, and the extralabel use of fluoroquinolones is prohibited in food-producing animals in the United States. Because of the risk of *Campylobacter* resistance, all fluoroquinolone formulations for poultry have been removed in the USA.

In order to provide continued monitoring of fluoroquinolone resistance bacteria from food animals, the National Antimicrobial Resistance Monitoring System (NARMS) performs routine surveillance of antibiotic resistance data from human clinical samples, slaughter samples and retail meat samples. In their most recent report (available at: http://www.cdc.gov/narms/), NARMS concluded that “Overall, ciprofloxacin resistance has been consistently low among *Salmonella* isolated from all sources. Similarly, ciprofloxacin resistance in *E. coli* was absent or very low (0–1.7%) in isolates from retail meats, chicken and cecal samples.” They also found that for *Campylobacter jejuni* in retail chicken samples, resistance to ciprofloxacin was at its lowest level to date (11%), while ciprofloxacin resistance in *C. jejuni* isolated from chicken slaughter samples has not declined (22% in 2013).

Pharmacokinetics

Extensive pharmacokinetic data is provided in Table 37.4. These are presented as examples because there are far more pharmacokinetic studies available in the literature than can be presented in this table. A literature search of pharmacokinetic studies in animals will reveal many available studies in the entire array of species treated by veterinarians – ranging from large animal species of elephants and whales, to mice and small invertebrate species.

Mammals are relatively consistent in elimination half-life and volume of distribution. Reptiles with lower renal clearance generally demonstrate longer half-lives – as long as 55 and 36 hours for enrofloxacin in alligators and monitor lizards, respectively (Papich, 1999). There may be an allometric relationship in pharmacokinetic parameters among mammals ranging in size from mice to cattle (Bregante et al., 1999; Cox et al., 2004). The allometric relationship was improved considerably when the pharmacokinetic parameters were corrected for the percentage of protein-unbound enrofloxacin in the plasma (Table 37.5).

Because most of these drugs are administered either once daily or as a one-time administration, the elimination half-lives shown in Table 37.4 may have little effect on clinical outcome. For example, it does not appear that differences in half-life can account for different clinical results for skin infection treatment in dogs because enrofloxacin, which has the shortest half-life, and marbofloxacin, which has a long half-life, have both been reported to be effective when administered once daily (Paradis et al., 1990; Carlotti et al., 1995; Carlotti, 1996; Gruet et al., 1997; Koch and Peters, 1996; Ihrke, 1996, 1998; Cester et al., 1996). In cattle and pigs, enrofloxacin is approved for either a one-time dose of 7.5–12.5 mg/kg, or 2.5–5 mg/kg once daily for three to five treatments. With either regimen, the outcome is the same. Likewise, danofloxacin is approved for use in cattle at a dose of 6 mg/kg administered twice, or a single dose of 8 mg/kg, with similar outcomes.

Although the volume of distribution varies among animals (and among studies), these differences have not translated into differences in clinical efficacy. Marbofloxacin and orbifloxacin, which have a volume of distribution in the range of 1–2– l/kg, achieve effective skin concentrations and appear as clinically effective as drugs

Table 37.4 Pharmacokinetic comparison of fluoroquinolones

Na = Data not available or not applicable.
Nd = Not determined, NR = not recommended.
$t_{1/2}$ = Half-life of the terminal portion of the plasma concentration vs. time curve.
AUC = Area under the curve of the plasma concentration vs. time curve.
C_{max} = Maximum plasma concentration after administration of oral or IM dose.
%*F* = Percentage of oral or IM administered dose absorbed (determined from comparison of IV dose).

[a] Half-life, volume of distribution, and AUC are from an IV dose unless otherwise noted. Apparent volume of distribution is typically from the area method. Where the dose was administered by a non-IV route, the Vd reported is Vd/F.

[b] Assay type = Assay using HPLC is able to distinguish between enrofloxacin and ciprofloxacin, and values shown in table represent enrofloxacin. Assays performed by bioassay represent the parent drug and active metabolites. Bioassay may include concentrations of ciprofloxacin.

[c] Registered dose with the FDA in the United States. In some European countries doses may vary or may not include the flexible range. In most cases, when treating non-*Pseudomonas* infections, the lowest dose in the range listed is used.

[d] After multiple dosing with ciprofloxacin, the C_{max} was 1.18 mg/ml and the 12 hr AUC was 9.58 mg/hr/ml.

[e] Oral absorption of ciprofloxacin estimated from a comparison of independent oral and IV studies.

[f] These parameters determined after administration of 5.8 mg/kg of enrofloxacin.

Note that in enrofloxacin studies, ciprofloxacin also was detected at varying concentrations (depending on species and study). Ciprofloxacin pharmacokinetics were measured in those studies but is not reported in this table. The ciprofloxacin data can be found in the studies referenced.

Table 37.5 Plasma/serum protein binding of fluoroquinolones in animals (% bound)

Animal	Enrofloxacin	Ciprofloxacin	Marbofloxacin	Orbifloxacin	Pradofloxacin
Camel	17–24				
Cattle	56, 36–45, 60, 46	31, 70, 19, 49.6, 33.8			
Sheep	69				
Horse	22	37		21 (at 1 μg/ml)	
Pig	27	23.6, 35			
Dog	15–25, 27, 35, 72	44, 18.5	9.1, 22	13.24 (at 1 μg/ml)	30–35 28.8–31
Rabbit	53, 50, 35, 6.0	33, 28			
Chicken	21	30			
Mouse	42				
Rat	50

When two or more values are listed, they represent results from independent studies.

such as enrofloxacin with a volume of distribution of 2.5–5 l/kg. Heinen (2002) demonstrated that even though approved doses may vary among enrofloxacin, marbofloxacin, and orbifloxacin in dogs, they are all capable of achieving pharmacokinetic–pharmacodynamic (PK-PD) targets (these targets are discussed in Section Pharmacokinetics / Pharmacodynamics). The data published (Bidgood and Papich, 2005, Walker et al., 1990, 1992; Messenger et al., 2012; Davis et al., 2007) or available from manufacturer technical information show that the fluoroquinolones, regardless of their volume of distribution and lipophilicity, achieve effective concentrations in tissues. Some exceptions are tissues not easily penetrated such as the central nervous system and eye.

Oral Absorption

Whether fluoroquinolones are administered with or without food has little effect on oral absorption. Feeding may delay the time to peak concentration (T_{max}), but this has little effect on clinical outcome because the extent of absorption, determined by the total AUC (area under the curve of the plasma concentration versus time curve) is not affected significantly. Administration with food has prolonged the terminal half-life when enrofloxacin was administered orally to reptiles (Papich, 1999), sheep, pigs (Gyrd-Hansen and Nielsen, 1994), and chickens (Anadón et al., 1995). This may be caused by a "flip-flop" pharmacokinetic effect introduced in Chapter 3 and discussed below in this section.

In clinical situations involving animals difficult to dose, fluoroquinolones may be added to a patient's food in order to provide a more convenient dosing form. For example, enrofloxacin tablets were placed in whole fish, which were fed to dolphins to produce good absorption (Linnehan et al., 1999), and enrofloxacin was injected into mice and fed to monitor lizards, also producing good absorption (Hungerford et al., 1997). Chewable tablets of enrofloxacin (Taste-Tabs) do not affect oral absorption (manufacturer's data).

In dogs, cats, and pigs, oral absorption of fluoroquinolones approaches 100% (Table 37.4), but in large animals, the extent of absorption has been less. Oral absorption of fluoroquinolones is variable in horses. Ciprofloxacin showed an oral absorption of only 6.8% in ponies (Dowling et al., 1995) and only 10% (mean) in adults (Yamarik et al., 2010). But enrofloxacin absorption is 63% (Giguère et al., 1996) in adult horses and 42% in foals (Bermingham et al., 2000). The value reported for adult horses is probably artificially high because the study used a bioassay that overestimates the concentration of enrofloxacin in plasma. With the exception of ciprofloxacin, other studies listed in Table 37.4 indicate relatively good oral absorption of these drugs in horses. Studies in ruminants produce conflicting results on oral absorption. In sheep, oral absorption was reported to be 61% (Pozzin et al., 1997), but absorption in ruminant calves was listed as less than 10% (Vancutsem et al., 1990). In sheep, absorption from oral administration was high (Bermingham et al., 2002). In addition, this study in sheep showed that when enrofloxacin was mixed with food and administered orally, absorption was high and half-life longer than after the IV dose. The long oral half-life was the result of slow release from the feed (possible adsorption) or slow emptying from the rumen ("flip-flop" effect). Absorption is also good in nondomestic ruminants such as the hoofstock kept in zoological parks (Gandolf et al., 2003; Gandolf, 2006). In camels (although not a true ruminant), oral absorption was reported to be negligible in one study (Gavrielli et al., 1995), but in another study absorption was 29% (mean) in alpacas and was capable of producing high enough concentrations to treat susceptible gram-negative pathogens at 10 mg/kg (Gandolf et al., 2005).

In birds, oral absorption of enrofloxacin is good, with effective levels being achieved by adding the drug to the bird's drinking water. This method of administration has been employed to treat sick pet birds (Flammer, 1998) and chickens (Knoll et al., 1999). However, as mentioned previously, administration to food-producing poultry is now prohibited in the United States. After continuous medication in the drinking water, steady-state plasma concentrations of enrofloxacin are 0.53 μg/ml (Knoll et al., 1999). In fish enrofloxacin absorption has been estimated to be 40–50% (Lewbart, 1998).

Intramuscular and Subcutaneous Injection

Absorption is virtually complete from intramuscular (IM) and subcutaneous (SC) injection. However, in some animals there was delayed absorption from IM or SC injections, which produced longer half-lives from these routes compared to IV administration (this is known as "flip-flop" absorption kinetics). Delayed absorption from injection is possibly due to a slow release from the injection site caused by tissue binding or tissue injury that disrupts blood flow. The large animal formulation of enrofloxacin (Baytril-100) is quite alkaline and can cause irritation at the injection site that can produce a delay in absorption.

In cattle, for example (Kaartinen et al., 1995), half-life was 1.68 hours from IV injection of enrofloxacin (5 mg/kg), but 5.9 and 5.55 hours from IM and SC injection, respectively, even though the extent of absorption was high. In the study by Davis et al. (2007) the half-life of enrofloxacin after a SC injection to calves at 12.5 mg/kg was 6.79 hours (mean), and 7.25 hours for the metabolite ciprofloxacin. For danofloxacin, the IV half-life in cattle was 0.9 hours and the IM half-life was 2.26 hours.

Metabolism

Metabolism of enrofloxacin to ciprofloxacin occurs via de-ethylation of the ethyl group on the piperazine ring. Activity against many bacteria is similar, but ciprofloxacin is somewhat more active than enrofloxacin against gram-negative bacilli, and enrofloxacin more active against *Staphylococcus* species (Riddle et al., 2000; Blondeau et al., 2012; Wetzstein, 2005; Grobbel et al., 2007). Together they produce an additive effect, and may broaden the spectrum compared to each drug alone. Other metabolites are produced from additional metabolism of ciprofloxacin, but these are minor and do not contribute to the antibacterial effects. There are also minor insignificant metabolites of some of the other drugs.

Examination of the extent of metabolism of enrofloxacin to ciprofloxacin in dogs and cats was reported in several studies (Küng et al., 1993a; Monlouis et al., 1997; Cester et al., 1996; Richez et al., 1997b; Kordick et al., 1997; Heinen, 1999; Seguin et al., 2004) in which high-pressure liquid chromatography (HPLC) was used to determine the specific concentrations of enrofloxacin and ciprofloxacin after enrofloxacin administration. The peak concentration (C_{max}) of ciprofloxacin accounts for approximately 20% in dogs and cats. Cattle produce more ciprofloxacin from enrofloxacin than most other species studied. The proportion of ciprofloxacin in plasma from administration of enrofloxacin to cattle has been measured as 25% (Richez et al., 1994), 31% (Foster et al., 2016a, 2016b), 37–39% (Idowu et al., 2010), and as high as 41% (Davis et al., 2007). The amount of ciprofloxacin produced in beef steers was slightly higher than dairy cows (ratio 64% and 59%, respectively) (Idowu et al., 2010). The studies by Davis et al. (2007), Foster et al. (2016a, 2016b), and Anadón et al. (1995) show that the ratio of ciprofloxacin: enrofloxacin concentrations in tissue can increase to greater than 1.0 after administration of enrofloxacin despite the low plasma concentrations of ciprofloxacin.

In pigs and foals there were only small traces of ciprofloxacin metabolized from enrofloxacin (Zeng and Fung, 1997; Bermingham et al., 2000; Richez et al., 1997a; Messenger et al., 2012). Older pigs may have greater metabolism to ciprofloxacin (Anadón et al., 1999).

In nonmammal species, the amount of ciprofloxacin produced from administration of enrofloxacin varies greatly. Studies in fish show that after administration of enrofloxacin, only 2% of the total fluoroquinolone concentration is comprised of ciprofloxacin (Lewbart et al., 1997). Reptiles and invertebrates tend to produce such small amounts of ciprofloxacin that it does not contribute to the plasma profile or AUC (Gore et al., 2005; Helmick et al., 1997; Howard et al., 2010; Hungerford et al., 1997; Papich, 1999; Raphael et al., 1994; Phillips et al., 2016; Rosenberg et al., 2016; Giorgi et al., 2013; James et al., 2003). In chickens, the concentrations of ciprofloxacin in plasma and tissues after administration of enrofloxacin are minimal (Knoll et al., 1999; Anadón et al., 1995).

If there are active metabolites produced, such as ciprofloxacin from enrofloxacin, this can cause errors in the interpretation of drug assays when a bioassay (microbiological assay) is used because a bioassay does not distinguish parent drug from active metabolite. Pharmacokinetic studies performed using bioassay techniques compared with studies using HPLC methods have demonstrated that bioassay can overestimate the combined enrofloxacin and ciprofloxacin concentrations in animals by as much as 70% for the AUC and 29% for the peak concentration (Cester et al., 1996). This finding agrees with another study in dogs: a microbiological assay overestimated the total enrofloxacin plus ciprofloxacin AUC determined by HPLC by as much as 30–70% (Küng et al., 1993b).

Excretion

The fluoroquinolones are primarily excreted via the kidneys by glomerular filtration and tubular excretion (Bregante et al., 1999). The role of tubular excretion has been demonstrated by showing that probenecid can decrease the clearance for some fluoroquinolones. For most of the drugs a major portion of the parent drug or metabolites can be recovered in the urine, with a smaller amount recovered in the feces. An exception is difloxacin (no longer marketed for animals), for which 80% of a dose was recovered in the feces and renal clearance accounted for less than 5% of the total systemic clearance.

Protein Binding

Protein binding is moderate for most of the fluoroquinolones (Table 37.5). The extent of protein binding has not limited distribution to tissues and has not produced a protein-binding interaction if displaced by another drug. Although protein binding is generally low, as shown in Table 37.5, there is a lack of consistency among studies, which is probably related to differences in technique used to measure protein binding. Protein binding can produce a reduction in antibacterial activity (Zeitlinger et al., 2008), but does not impair distribution to tissues. When in vivo ultrafiltration techniques were used in animals, the free drug concentration (protein unbound) in tissue fluid exceeded the fraction unbound in plasma (Davis et al., 2007; Bidgood and Papich, 2005; Foster et al., 2016a, 2016b; Messenger et al., 2012; Hauschild et al., 2013).

Tissue Distribution

Distribution to most tissues is listed for each drug in the manufacturer's package insert or Freedom of Information (FOI) summary. Specific studies for enrofloxacin have been conducted to show that it distributes to bone (Duval and Budsberg, 1995), prostate (Dorfman et al., 1995), and skin (DeManuelle et al., 1998). Specific studies using in vivo ultraviltration techniques show that distribution of the unbound drug (microbiologically active concentration) generally exceeds the value predicted by the unbound concentration in plasma (Davis et al., 2007; Bidgood and Papich, 2005; Foster et al., 2016a, 2016b; Messenger et al., 2012; Hauschild et al., 2013). Thus, extracellular tissue fluid concentration of the unbound fluoroquinolone will generally be in equilibrium with, or exceed, plasma drug concentrations.

In tissues in which the fluoroquinolones accumulate intracellularly, high tissue concentrations are reported because measurement of tissue concentrations is typically performed by homogenizing the tissue, which disrupts cells and releases intracellular concentrations. Tissue concentrations measured in this manner represent both intracellular and extracellular concentrations and can overestimate active drug concentrations. Some tissues, such as liver and kidney, may have fluoroquinolone concentrations several-fold higher than corresponding plasma concentrations.

Fluoroquinolones attain moderately high intracellular concentrations in macrophages and neutrophils. The cellular: extracellular (C : E) ratio is often greater than 4, but usually less than 10 compared to plasma concentrations (Pascual et al., 1990; Tulkens, 1990; Easmon and Crane, 1985; Drusano et al., 1998). The reason for intracellular concentration is unclear (Drusano et al., 1998; Van Bambeke et al., 2006). Fluoroquinolones are moderately lipophilic and also have a slower efflux from these cells. In humans, ciprofloxacin has an intracellular half-life of 6.7 hours in neutrophils versus 3.7 hours in serum (Easmon et al., 1986).

Concentrations in urine may be several times higher than plasma concentrations. Concentrations of enrofloxacin, marbofloxacin, and orbifloxacin in urine of dogs are listed by the manufacturer to be 43, 40, and 84.5 μg/ml, respectively. One exception to the high urine excretion is difloxacin (no longer marketed) for which less than 5% of the dose is cleared in the urine. Fluoroquinolones are among the few drugs that adequately penetrate the prostate gland in sufficient concentrations to treat prostatitis caused by infection. Enrofloxacin concentration (determined by bioassay) in the prostatic fluid and prostate tissue exceeded serum concentration at all times after administration (Dorfman et al., 1995). There were no differences in tissue concentrations when infected prostate was compared to healthy tissue. Concentrations of other fluoroquinolones in prostate tissue have been reported by the manufacturers to be 3.36, 5.6, and 1.35 μg/gram for difloxacin, marbofloxacin, and orbifloxacin, respectively.

Pharmacokinetics / Pharmacodynamics

Minimum inhibitory concentration values for bacteria are listed in Table 37.3 and breakpoints for susceptibility testing listed in Table 37.2. Even though there are differences in potency among the currently available fluoroquinolones, a pattern is apparent: *Pasteurella,* such as the strains found in skin wounds and cause of respiratory infections in livestock, are the most susceptible; wild-type strains of the gram-negative enteric bacilli (e.g., *E. coli* and *Klebsiella*) also have low MIC values. The gram-positive cocci such as *Staphylococcus aureus* and the common canine skin pathogen *Staphylococcus pseudintermedius* have MIC values at a somewhat higher range, and *P. aeruginosa* has MIC values that are among the highest for susceptible bacteria. Although not listed in Table 37.3, streptococci, enterococci, and anaerobic bacteria typically have MIC values high enough that they are usually in the resistant category. Fluoroquinolones of the third generation, such as pradofloxacin (Figure 37.3) have lower MIC values for gram-positive bacteria than the second-generation drugs.

Fluoroquinolones are bactericidal and they act in a concentration-dependent manner rather than a time-dependent manner. The exposure to the bacteria has been measured by using the maximum peak concentration (C_{max}) in relation to the bacteria MIC and expressed as the C_{max} : MIC ratio. A C_{max} : MIC ratio that is at least 8–10 times (i.e., a peak concentration that is 8–10 times the MIC) is desirable. A high C_{max} : MIC ratio is optimal to decrease emergence of resistance (Drusano et al., 1998; Blaser et al., 1987), but the area-under-the-curve (AUC) to MIC ratio (AUC : MIC) may be used to predict efficacy. When low C_{max} : MIC ratios were achieved, the mutant strains that occur spontaneously were not suppressed, and resistance emerged because these mutant strains have MIC values that are at least four to eight times that of the parent (wild-type) strain (Drusano et al., 1993).

The area under the curve (AUC) for a 24-hour dose interval in relation to the MIC is expressed as the AUC_{24} : MIC ratio. It is understood that the AUC represents the protein-unbound concentration. An AUC : MIC ratio of 125–250 has been associated with the optimum antibacterial effect (Lode et al., 1998; Hyatt et al., 1995; Dudley, 1991; Nicolau et al., 1995; Wright et al., 2000). According to USCAST (2015, http://www.uscast.org/) the free-drug AUC : MIC targets for a 2-$\log_{10}$ reduction (99% reduction) is 140, 65, 187, and 34 for Enterobacteriaceae, *Pseudomonas aeruginosa, Staphylococcus aureus*, and *Streptococcus*, respectively, based on experimental conditions.

These targeted C_{max} : MIC and AUC : MIC ratios were based on in vitro or in vivo studies performed with immunosuppressed laboratory animals or on clinical studies involving people with serious illness (Forrest et al., 1993; Blaser et al., 1987; Sullivan et al., 1993).

As reviewed by Wright et al., (2000), there is evidence that for some clinical situations, AUC : MIC ratios as low as 30–55 are necessary for a clinical cure, since the study in which 125 was cited involved critically ill human patients. The USCAST evaluation cited above (2015, http://www.uscast.org/) lists clinical AUC : MIC targets above 70 for Enterobacteriaceae and *Pseudomonas aeruginosa,* and 34 for *Streptococcus*. A lower AUC : MIC ratios for stereptococci than for gram-negative bacteria was also shown by Ambrose and Grasela (2000), in which they presented data and reviewed the relevant publications.

Some veterinary studies have shown that the ratios necessary for clinical results may not be as high as reported from studies in laboratory rodents or people (Lees and Aliabadi, 2002).Many veterinary patients treated with fluoroquinolones are not as immunosuppressed as laboratory animals or ill as people that participated in some clinical studies. Therefore the targeted ratios may be less in veterinary patients than cited above. For example, if one compares the AUC in Table 37.3 to representative MIC values from Table 37.4, lower AUC : MIC ratios in some patients appears adequate.

Dose Guidelines

Specific clinical uses are discussed in this chapter for the major species. Doses listed in Tables 37.4 and 37.6 cover a wide MIC range among susceptible bacteria, from as low as 0.03 μg/ml to as high as 1.0 μg/ml. The upper end of the dose is limited by safety (such as gastrointestinal or central nervous system effects); the lower dose is determined by efficacy. There is no advantage to frequent dosing (multiple times/day) as long as a sufficiently high C_{max} : MIC or the same AUC : MIC is achieved; therefore, the doses discussed for mammals and listed in Table 37.4 are intended for once-daily administration, or for some uses in cattle and pigs, a single high dose may be used for respiratory infections (Table 37.7). The single high dose regimen has not been tested for animals other than pigs and cattle.

Clinical Use

Dogs and Cats

The administration of fluoroquinolones to dogs and cats constitutes one of the largest applications of these drugs for veterinary medicine. They have been used for over 25 years for infections of the skin, soft tissue, oral cavity, urinary tract, prostate, ear, wounds, respiratory tract, and bone (Paradis et al., 1990; Ihrke and DeManuelle, 1999; Ihrke, 1996; Ihrke et al., 1999; Carlotti et al., 1999; Griffin, 1993; Hawkins et al., 1998; Dorfman et al., 1995; Cotard et al., 1995). The first veterinary quinolone was enrofloxacin, and veterinarians now have experience with marbofloxacin, orbifloxacin, and pradofloxacin (and occasionally others in different countries) (Table 37.1). The efficacy of the fluoroquinolones was established for indications listed on the labels approved by the US Food and Drug Administration (FDA), European authorities, and licensing in other countries.

At the approved doses, orbifloxacin, enrofloxacin, and marbofloxacin reach therapeutic targets in dogs against susceptible bacteria, even though the doses and pharmacokinetics vary among the drugs (Heinen, 2002). The efficacy of enrofloxacin and marbofloxacin has been

Table 37.6 Dose recommendations for enrofloxacin in exotic animals

Animal	Dose	Route	Interval	Reference
Alligator	5 mg/kg	IV, oral	Every 96 hr	Helmick et al., 1997
Savanna monitor	5 mg/kg (10 mg/kg for *Pseudomonas* spp.)	IM, oral	Every 96 hr	Hungerford et al., 1997
Burmese python	5 mg/kg (higher doses for *Pseudomonas* spp.)	IM	Every 48 hr	Young et al., 1997
Indian star tortoise	5 mg/kg	IM	Every 24 hr	Raphael et al., 1994
Red-eared slider	5 mg/kg	oral, IM	Every 72 hr (oral), every 48 hr (IM)	James et al., (unpublished data)
Gopher tortoise	5 mg/kg	IM	Every 24–48 hr	Prezant et al., 1994
Bottlenose dolphin	5 mg/kg	oral	Every 24 hr	Linnehan et al., 1999
Parrot and cockatoo	7.5–15 mg/kg	oral	Every 12 hr	Flammer, 1998
Fish (ornamental)	5 mg/kg	IM, oral, or IP	Every 48 hr	Lewbart, 1998

These recommendations are based on an analysis of pharmacokinetic data and limited clinical experience. There have been no well-controlled efficacy studies or safety studies in these animals.

demonstrated specifically for canine pyoderma, including deep pyoderma, through published reports (Ihrke and DeManuelle, 1999; Ihrke, 1996; Paradis et al., 1990; Carlotti et al., 1999; Ihrke et al., 1999; Koch and Peters, 1996). Although efficacy has been shown for treating pyoderma in animals, guidelines for treatment recommend that they not be used as a first-choice agent (designated as "second tier" or "second-line" antibiotics) (Beco et al., 2013; Hillier et al., 2014). Another common use of fluoroquinolones in small animals is for treatment of urinary tract infections (Weese et al., 2011). In some patients, a 3-day course of treatment is sufficient for a clinical cure (Westropp et al., 2012).

In addition to treatment of infections in these common sites, fluoroquinolones have been used to treat rickettsial infections (Breitschwerdt et al., 1990, 1999) and *Bartonella* infections in cats (Kordick et al., 1997). Against *Rickettsia rickettsii*, enrofloxacin is equally as effective as doxycycline or chloramphenicol (Breitschwerdt et al., 1990), but the success for eliminating *Bartonella* in cats has been equivocal (Kordick et al., 1997). Enrofloxacin has been used successfully to treat acute ehrlichiosis in dogs caused by *E. canis* and *E. platys* at a dosage of 5 mg/kg once daily for 15 days (Kontos and Athanasiou, 1998). However, success in treating chronic ehrlichiosis has not been demonstrated. Fluoroquinolones also have been used to treat infections caused by *Mycoplasma* and *Mycobacteria*. Although the activity against *Mycoplasma* can be variable (Hannan et al., 1997), it has been effective for some opportunistic mycobacterial infections in cats (Studdert and Hughes, 1992).

Ciprofloxacin Use in Dogs and Cats

Despite the availability of safe and effective veterinary-labeled fluoroquinolones (enrofloxacin, marbofloxacin, orbifloxacin), ciprofloxacin oral tablets, available in a generic formulation for people, are increasingly being used for treatment in dogs. Veterinarians in the USA can legally prescribe unapproved human-label drugs to non-food producing animals according to the Animal Medicinal Drug Use Clarification Act (AMDUCA) of 1994. The oral absorption in dogs, according to published studies, is variable, inconsistent, and lower than in humans. Estimates from some studies (Abadia et al., 1994, 1995; Walker et al., 1990), indicate that oral absorption may approach 74 to 97%, but has been as low as 42%. In a more recent study (Papich, 2012) the average oral absorption was 58.4%, but with high variability (coefficient of variation, CV 45.4%). The range in oral absorption was from approximately 30% to 98%. The variable oral absorption appeared to be caused by the incomplete and inconsistent dissolution of the human generic oral tablet. A larger population pharmacokinetic study (Papich, 2017) showed a low and variable absorption with a C_{max} of 1.19 μg/ml, AUC of 13.8 μg h/ml, and half-life of 4.35 hours. Simulations using a dose of 25 mg/kg oral, once per day

Table 37.7 Single high dose for fluoroquinolones used in veterinary medicine

Drug	Brand Name(s)	Species	Dose
Enrofloxacin	Baytril, and generic	Cattle	7.5–12.5 mg/kg SC
Enrofloxacin	Baytril, and generic	Pigs	7.5 mg/kg, SC
Danofloxacin	Advocin	Cattle	8 mg/kg, SC

would reach therapeutic targets only for bacteria with MIC values of 0.06 μg/ml, or less, which is far less than the human breakpoint for susceptible bacteria (Table 37.2).

Studies with ciprofloxacin in cats (Albarellos et al., 2004) showed low oral absorption at 10 mg/kg (33%). The authors concluded that a dose of 10 mg/kg every 12 hours might be sufficient for susceptible gram-negative bacteria with low MIC values, but this dose would likely not meet therapeutic targets against other bacteria.

Pradofloxacin Use in Dogs and Cats

Pradofloxacin (Veraflox®) is one of the newest fluoroquinolones (sometimes referred to as a third-generation fluoroquinolone; see Section Structure–Activity Relationships for differences). Other drugs that meet this definition are the human drugs grepafloxacin, gatifloxacin, gemifloxacin, and moxifloxacin. Because the older, second-generation fluroroquinolones (e.g., enrofloxacin, marbofloxacin, orbifloxacin) have less activity against gram-positive cocci and anaerobic bacteria (Figure 37.3), prafofloxacin have improved activity against some organisms in veterinary medicine (Blondeau et al., 2004; Lees, 2013). Pradofloxacin MIC_{90} values are 0.06–0.125 μg/ml for *Staphylococcus* spp., 0.06 μg/ml for *E. coli*, and 0.015 μg/ml for *Pasteurella multocida*. Pradofloxacin has been evaluated in dogs and cats for skin, soft-tissue, oral, and urinary tract infections (deJong et al., 2004; Spindel et al., 2008; Hartmann et al., 2008b; Litster et al., 2007; Mueller and Stephan, 2007). Pharmacokinetic studies are also available (Hartmann et al., 2008a; Hauschild et al., 2013). Susceptibility data indicate that it is more active than other fluoroquinolones against bacterial isolates from dogs and cats (deJong et al., 2004; Silley et al., 2007; Stephan et al., 2007b) (Figure 37.3). Because it is active against two targets of fluoroquinolones (topoisomerase IV and DNA gyrase) development of resistant mutants may be less likely (Wetzstein, 2005; Stephan et al., 2007a).

At a dose of 3 mg/kg orally it was effective for treatment of urinary tract infections in dogs and at 5 mg/kg was effective for canine pyoderma (Mueller and Stephan, 2007). At a dose of 5 mg/kg in a 2.5% oral suspension it was effective for urinary tract infections in cats (Litster et al., 2007).

Pradofloxacin is approved in the USA for cats only, and in other countries for both dog s and cats. Pradofloxacin has been safe in cats with respect to ocular lesions (Messias et al., 2008). The European label and US label are slightly different. In Europe, pradofloxacin is indicated for the treatment of dogs and cats for infections caused by *Staphylococcus pseudintermedius*, superficial and deep pyoderma caused by susceptible strains of *S. pseudintermedius*, acute urinary tract infections caused by susceptible strains of *E. coli* and *S. pseudintermedius,* and adjunctive treatment to mechanical or surgical periodontal therapy in the treatment of infections of the gingiva and periodontal tissues caused by susceptible strains of anaerobic organisms (*Porphyromonas* spp. and *Prevotella* spp.) The registered dose is 3 mg/kg once daily for 7–35 days, depending on the indication. For cats, pradofloxacin 25 mg/ml oral suspension is indicated for the treatment of acute infections of the upper respiratory tract caused by *P. multocida, E. coli,* and *S. pseudintermedius* and for the treatment of wound infections and abscesses caused by *P. multocida* and *S. pseudintermedius* in cats. The US label is more limited and only applies to cats for treatment of skin infections (wounds and abscesses) in cats caused by susceptible strains of *P. multocida, Streptococcus canis, Staphylococcus aureus, Staphylococcus felis*, and *S. pseudintermedius*. The dose in cats according to US labeling is 7.5 mg/kg daily and 5 mg/kg once daily on European labels. Breakpoints are established for testing pathogens from dogs and cats (Table 37.2).

Small Mammals

Enrofloxacin and other fluoroquinolone antibiotics are used frequently in small mammals such as rabbits, mice, rats, and exotic species for skin and visceral infections (Göbel, 1999; Cabanes et al., 1992; Broome and Brooks, 1991). Fluoroquinolones are popular for treatment in small mammals because of potent activity against gram-negative pathogens affecting these animals and have good oral absorption. Oral tablets of fluoroquinolones have been administered directly or crushed to make a suspension that can be conveniently administered orally to the small mammals mixed with water, fruit, or some other palatable flavoring. When mixed in a compounded formulation with these vehicles, enrofloxacin was stable for 56 days (Petritz et al., 2013). Another study showed that marbofloxacin tablets could be crushed and mixed with flavored vehicles for rabbits and was stable for 14 days (Carpenter et al., 2009).

Small mammals such as rodents and rabbits are prone to gastrointestinal disturbances and enteritis caused by overgrowth of bacteria, especially *Clostridium* organisms after administration of β-lactam and macrolide antibiotics. Because fluoroquinolones are not active against the anaerobic bacteria that compete with *Clostridium* organisms, bacterial overgrowth of pathogenic opportunistic bacteria has not been a problem as it has with other drugs, such as penicillins or macrolides.

Of the available drugs, enrofloxacin has been the most extensively studied. The doses listed in textbooks and review articles for mice, gerbils, hamsters, rats, and guinea pigs are 2.5–5.0 mg/kg up to 10–20 mg/kg IM, SC, or orally administered twice daily. The pharmacokinetics has been reported (Table 37.4), and there is some experience with the drug's efficacy. In rabbits oral enrofloxacin has been effective for improving clinical signs associated with pasteurellosis. The recommended dose of enrofloxacin for rabbits is 5 mg/kg IM, SC, or oral. Although it does not completely eradicate the bacteria in pasteurellosis in rabbits, it is considered the drug of choice (Göbel, 1999; Broome and Brooks, 1991). Marbofloxacin and moxifloxacin also have been studied in rabbits and pharmacokinetics were favorable (Abo-El-Sooud and Goudah, 2010; Fernández-Varón et al., 2005; Carpenter et al., 2009). The recommended dose of marbofloxacin for rabbits is 5 mg/kg oral, once every 24 hours (Carpenter et al., 2009).

Reptiles

The use of fluoroquinolones in reptiles has become popular because of their activity, safety, and convenience of administration (Papich, 1999; Jacobson, 1999; Rosenthal, 1999). Enrofloxacin has been studied more than any other drug in this class in reptiles. It is active against gram-negative organisms often implicated in serious infection of reptiles, including *Salmonella* spp., *Aeromonas hydrophilia, Klebsiella* spp., and *P. aeruginosa,* and its pharmacokinetics has been summarized in a review (Papich, 1999). It shows remarkable differences among the reptiles, but generally the elimination is much longer than in mammals or birds, which allows long dose intervals – as long as every 96 hours in some species (Table 37.4). The elimination rate of drugs in reptiles varies with the animal's body temperature, because body temperature affects metabolic rate. When enrofloxacin is administered, there is variable metabolism to the active metabolite ciprofloxacin among the reptiles. Elimination half-life ranged from 55 hours in alligators to 5.1 hours in tortoises (Young et al., 1997; Raphael et al., 1994; Helmick et al., 1997; Hungerford et al., 1997; Prezant et al., 1994). Monitor lizards, and pythons had half-lives of 36 and 17.6 hours, respectively. Turtles have long half-lives ranging from 18 hours to more than 50 hours that allow for infrequent administration of once per day to once per week (Table 37.4). Analysis of pharmacokinetic data and appraisal of clinical experience (Jacobson, 1999; Papich, 1999) suggest a range of doses (Table 37.6), but safety and efficacy studies have not been performed.

Pharmacokinetic studies have shown good absorption of enrofloxacin from IM administration, and this route may prolong the half-life, probably because of delayed absorption from the injection site. Although some authors have suggested that oral administration should be avoided in reptiles because of unreliable absorption, absorption was good after oral administration to alligators, lizards, and turtles (Helmick et al., 1997; Hungerford et al., 1997; James et al., 2003). Because of slow gastrointestinal transit time, oral absorption may prolong the half-life ("flip-flop" effect).

Birds

The fluoroquinolones are an important group of antibiotics for pet birds and exotics kept in zoo collections, but they are prohibited in poultry in the United States. Administration is via drinking water, oral gavage, or by injection. Fluoroquinolones have the advantage of good activity against bacterial pathogens important to birds, including *E. coli, Klebsiella* spp., *Pseudomonas* spp., *Staphylococcus* spp., and for treatment of *Chlamydophila psittaci* (formerly called *Chlamydia psittaci*). Resistance is possible for *E. coli* and *Pseudomonas* spp., however, and activity against gram-positive cocci (e.g., streptococci and enterococci) is low. Although there is in vitro susceptibility of *Chlamydophila* to fluoroquinolones, experience suggests that enrofloxacin can decrease clinical signs but not eliminate the infections (Flammer, 1998). Therefore, fluoroquinolones are not recommended for mass medication of pet birds, and doxycycline is still the choice for this indication (discussed in Chapter 34).

For pet birds, the dose is higher than for mammals because the clearance is faster and metabolic rate is higher. A comparison of enrofloxacin, danofloxacin, and marbofloxacin in quails (Haritova et al., 2013) showed half-lives of 2–4 hours, and variable oral absorption among drugs (data not shown in Table 37.4). Enrofloxacin had much lower oral absorption in these birds than the other drugs studied. The Haritova paper also included tables of pharmacokinetic parameters for other birds. Pharmacokinetic studies of enrofloxacin in birds indicate a dose of 15 mg/kg IM or orally every 12 hours (Flammer, 1998; Flammer et al., 1991). Enrofloxacin has been administered to ducks at a dose of 10 mg/kg every 24 hours IM or orally. Enrofloxacin added to drinking water at a concentration of 0.3–0.5 mg/ml has been used to treat susceptible bacteria (Flammer et al., 1990). Enrofloxacin was well absorbed by this route, and as long as the bird is drinking, effective plasma concentrations can be attained. One concern with the IM injection is that it can produce irritation at the site of injection, which is problematic because birds have a limited muscle mass into which one can inject.

Fish

Fluoroquinolones have been considered for treatment of infections in ornamental fish and for use in aquaculture. These drugs are active against important gram-negative bacterial pathogens of fish, and they appear to be well tolerated. Enrofloxacin has been administered orally to rainbow trout kept in water maintained at 10° and 15°C.

Although oral absorption is less than in mammals, it was sufficient to produce effective plasma concentrations (Bowser et al., 1992). MIC values for pathogens infecting fish range from 0.0064 to 0.032 µg/ml for the most sensitive organisms to 0.25–0.45 µg/ml for *Streptococcus* spp. Thus the dose of 5 mg/kg should produce effective plasma concentrations for most susceptible pathogens (Bowser et al., 1992). In Atlantic salmon, enrofloxacin administered at 10 mg/kg intraperitoneally, intramuscularly, and orally was well absorbed from these routes, with no advantage of one route over another, but it produced a wide range of half-lives and Vd. Oral absorption in salmon was 46%, but the authors concluded that at 5 mg/kg this route would be suitable for therapeutic treatment (Stoffregen et al., 1997). Tissue concentrations were high, with concentrations detected at 120 hours after dosing.

Enrofloxacin has also been studied in red pacu as a model for other ornamental fish (Lewbart et al., 1997). For treatment of bacterial infections in ornamental fish, Lewbart (1998) recommends enrofloxacin at a dose of 5 mg/kg. This can be administered IM, IP, or orally with a recommended interval of every 48 hours, but the IM route produces the most predictable plasma concentrations. The oral dose can be prepared as a mixture of 0.1% in fish food (10 mg per 10 g of food). Enrofloxacin also has been added to water and used as a bath for fish in which the drug is absorbed across the surface area of the gill to produce systemic levels. In this treatment 2.5–5.0 mg enrofloxacin per liter is used as a 5-hour treatment bath repeated every 24 hours (Lewbart et al., 1997). The resulting peak plasma concentration after such a treatment was 0.17 µg/ml. Studies of the stability of enrofloxacin in water at various degrees of salinity and pH showed enrofloxacin to be stable when added to a water bath (unpublished results from the laboratory of the author, MGP). However, the effect of the drug on nitrifying bacteria in the water should be considered.

Invertebrate marine species also have been examined. Studies in cuttlefish showed that clearance was surprisingly rapid, and doses of 5 mg/kg every 12 hours would be necessary to maintain effective concentrations (Gore et al., 2005). However, the same study indicated that systemic absorption from immersion of cuttlefish in an enrofloxacin medicated bath was possible. In sea urchins and sea stars population pharmacokinetic methods were used to examine injections and water bath treatments (Phillips et al., 2016; Rosenberg et al., 2016). In sea urchins and sea stars the half-life was long (39 hours, 43 hours, respectively), and concentrations were maintained above a level needed to treat susceptible bacteria. The medicated bath treatment produced lower concentrations, but may still be adequate for treating some susceptible bacteria.

Horses

In horses, there is no fluoroquinolone approved for use in the USA, but these drugs, especially enrofloxacin, are often used in horses to treat infections that may be resistant to other common equine antimicrobials. Several pharmacokinetic studies have generated data for these drugs in horses to guide dosing protocols. These data, as well as clinical experience, have shown that this class of drugs can be valuable for treating infections in horses. Their valuable properties include the following: (i) ability to administer by oral, IV, and IM routes, although only enrofloxacin is available in an injectable formulation in the United States; (ii) spectrum of activity that includes staphylococci and gram-negative bacilli such as *Klebsiella pneumoniae, E. coli,* and *Proteus* spp.; (iii) spectrum of activity that does *not* include anaerobic bacteria, therefore posing less risk of disrupting bacteria in the intestine than other oral antimicrobials; and (iv) good safety profile in adult horses. Despite these advantages, the oral absorption is less than other animals, and more variable. Therefore, the analysis of susceptibility testing breakpoints resulted in lower values for equine isolates compared to other animals (Table 37.2). These breakpoints are based on an oral dose of enrofloxacin of 7.5 mg/kg once daily.

The oral absorption of enrofloxacin in horses has generally been in the range of 50–70% (Table 37.4). Most bacteria that infect horses are susceptible, but resistance is expected for streptococci and anaerobes. Strains of *Pseudomonas aeruginosa* may be resistant or only moderately susceptible. *Rhodococcus equi* can be resistant, and success in treating *Rhodococcus* infections in horses with enrofloxacin has not been encouraging (see Chapter 36 for recommendations to treat *Rhodococcus* in horses). Based on the studies cited in this section, as well as clinical experience to date, an injectable dose of enrofloxacin at 2.5 to 5 mg/kg once daily or an oral dose of 7.5 to 10 mg/kg once daily is recommended (Giguère et al., 1996). The higher oral dose is used to accommodate the decreased systemic availability from an oral dose. For orbifloxacin (Orbax), an oral dose of 5 mg/kg once daily is recommended (Davis et al., 2006). These doses meet PK-PD criteria for susceptible bacteria discussed earlier in this chapter. For marbofloxacin (Zeniquin), IV doses of 2 mg/kg q 24 h may be adequate for treatment of most gram-negative infections caused by Enterobacteriaceae (Bousquet-Mélou et al., 2002; Peyrou et al., 2004; Carretero et al., 2002). However, this dose would not be adequate for many gram-positive bacteria, such as *Staphylococcus* spp., with MIC values of 0.25 µg/ml or higher. The injectable formulation is not available in the United States; therefore, oral tablets of marbofloxacin would be required for administration. Marbofloxacin has systemic availability of approximately 62% in horses.

(Bousquet-Mélou et al., 2002). Oral dosing at 2 mg/kg may be adequate for susceptible Enterobacteriaceae with MIC values less than 0.2 μg/ml, but not for other bacteria. Doses higher than 2 mg/kg have not been studied in horses. Ciprofloxacin is not recommended because the oral absorption was poor in ponies and adult horses (Dowling et al., 1995; Yamarik et al., 2010). Enteritis may occur in horses from ciprofloxacin owing to the poor absorption and disruption of intestinal bacteria (Yamarik et al., 2010).

The method of administration for horses has been to (i) crush up tablets used in small animals; (ii) administer the injectable solution (2.27% or 10%) IM (neck muscle) or IV; or (iii) administer the concentrated 10% solution orally (Baytril-100 cattle formulation). All these methods appear to produce adequate plasma concentrations, except for the administration of the concentrated 10% solution (Baytril-100) orally. This solution has produced inconsistent and incomplete absorption in horses, possibly because of its insolubility in solutions of low pH (Haines et al., 2000). In other studies, absorption of this solution was better when horses were fed (Boeckh et al., 2001). This solution also has been associated with oral mucosal lesions in horses. Some clinicians have produced more consistent oral absorption and reduced mucosal irritation when the 100 mg/ml solution was compounded into a gel (Epstein et al., 2004).

Moxifloxacin (Avelox) is a human drug of this group and has been used on a limited basis for treatment of infections in dogs and cats caused by bacteria that have been refractory to other drugs. When administered to horses, moxifloxacin had favorable pharmacokinetics that could make it suitable for oral use in horses (Gardner et al., 2004). However, oral administration also produced diarrhea in the experimental horses studied, and one of these horses tested positive for *Clostridium difficile* toxins A and B. The spectrum of activity of this drug may be broad enough to disrupt the normal flora.

Ruminants

In cattle and sheep, the pharmacokinetics of enrofloxacin and danofloxacin has been reported (Table 37.4) and doses have been derived from these studies, clinical trials, or the approvals in various countries. Enrofloxacin and danofloxacin are approved for use in cattle in the United States and some European countries. These fluoroquinolones have been highly active against important pathogens causing bovine respiratory disease (BRD) in cattle. The MIC_{90} values listed for *Histophilus somni, Mannheimia haemolytica,* and *P. multocida* are 0.03, 0.06, and 0.03 μg/ml, respectively. Extralabel use is not allowed in food-producing animals (see Chapter 52 and 55). For enrofloxacin, the dose ranges from a single SC dose of 7.5–12.5 mg/kg, or treatment for 3 days at 2.5–5.0 mg/kg, once daily, SC. The withdrawal time is 28 days. Comparisons of enrofloxacin pharmacokinetics between dairy cows and beef steers did not show significant differences in parameters between the groups (Idowu et al., 2010). It is not approved for lactating cattle or dairy calves, but disposition into milk of lactating cows has been studied. Enrofloxacin is highly excreted in milk. (See Section Administration to Nursing, Pregnant, or Young Animals.)

Danofloxacin (Advocin®) is also approved for treatment of BRD in cattle. Danofloxacin contains either 25 mg/ml or 80 mg/ml of danofloxacin as the mesylate salt, depending on the country in which it is approved. It has a broad spectrum of activity, similar to enrofloxacin, including bovine isolates of *Pasteurella, Mannheimia haemolytica*, *Haemophilus somnus*, and *Mycobacterium bovis.* The breakpoints are listed in Table 37.2. The US approved label dose allows either a dose of 6 mg/kg twice, 48 hours apart, or a single dose of 8 mg/kg SC. The European formulation of 2.5% also allows for the intramuscular or intravenous routes at a dosage rate of 1.25 mg/kg. At this dose, three treatments should be given at 24-hour intervals. However, the higher dose is preferred because it is more likely to hit PK-PD targets. (PK-PD properties are discussed in Section Section Pharmacokinetics / Pharmacodynamics.)

The danofloxacin manufacturer reported a half-life of 4.35, and volume of distribution of 3.6 l/kg at the label dose of 6 mg/kg. Some earlier work at lower doses (Giles et al., 1991) reported similar results (half-life 4 hours and volume of distribution of 2.76 l/kg). Lung tissue concentrations were higher than the corresponding serum concentration and persist above the MIC for 12–24 hours after injection (Giles et al., 1991; Apley and Upson, 1993). In a comparison between enrofloxacin and danofloxacin (TerHune et al., 2005), danofloxacin produced plasma concentrations that were 56 times the MIC of 0.03 μg/ml, which is the MIC reported for North American BRD isolates. Although it is not legal to use fluroquinolones in the USA in an off-label manner, studies have also shown danofloxacin to be effective for bacterial enteritis in calves and is registered for this use in other countries.

Marbofloxacin (Forcyl®) 160 mg/ml solution is approved in some countries for use in cattle, and has also been tested in buffalo calves (Baroni et al., 2014). The dose studied in cattle has been 2 mg/kg per day for 3–5 days, or a single injection of 10 mg/kg, injected IM in the neck muscle. Vallé et al. (2012) concluded that a single high dose was as effective, and may reduce resistance, compared to lower doses.

Pigs

Enrofloxacin is approved in the United States for use in pigs for treatment and control of swine respiratory disease (SRD) associated with *Actinobacillus pleuropneumoniae, Pasteurella multocida, Haemophilus parasuis*, and *Streptococcus suis*. Efficacy and microbiological data (MIC distribution) have been reported for these pathogens in pigs (Grobbel et al., 2007). The pharmacokinetics of fluoroquinolones in pigs are shown in Table 37.4 and breakpoints for testing shown in Table 37.2. Most of the pharmacokinetic studies in pigs (Nielsen and Gyrd-Hansen, 1997; Anadón et al., 1999; Wiuff et al., 2002; Bimazumute et al., 2009) showed that the half-life of enrofloxacin ranged from 9 to12 hours. These studies were performed at a low dose. At the dose most often used clinically, 7.5 mg/kg once SC, the pharmacokinetics and tissue distribution were reported by Messenger et al. (2012). The Messenger study showed that at the dose of 7.5 mg/kg, the free drug concentrations in tissue exceed the predicted unbound concentration and attained target levels for swine respiratory pathogens. In all but one study, the ciprofloxacin concentrations were low and difficult to quantify, accounting for less than 10% of the corresponding enrofloxacin concentrations, or were below the assay limit of quantification (LOQ). One study (Anadón et al., 1999) that used older pigs, was an outlier and reported ciprofloxacin concentrations that were 51.5% of the corresponding enrofloxacin concentrations.

Marbofloxacin (Forcyl®, Marbocyl®) 16%, 10%, or 2% solution for IV or IM injection is approved in some countries (not the USA) for treatment of swine respiratory disease and metritis–mastitis–agalactia syndrome in sows. The dose in pigs is 2 mg/kg once daily for 3–5 days, or 8 mg/kg administered once, IM. The absorption from IM injection in pigs is not affected by the dose or concentration of the formulation (Schneider et al., 2014).

Administration to Nursing, Pregnant, or Young Animals

Nursing Animals

Distribution also has been measured for milk in rabbits and cattle. Enrofloxacin is excreted rapidly in the milk after administration. In cattle after administration of enrofloxacin at 5 mg/kg, enrofloxacin concentrations in milk parallel the concentrations in serum, with a C_{max} of 1.3–2.5 μg/ml, but concentrations of the active metabolite ciprofloxacin exceed those of enrofloxacin (Kaartinen et al., 1995; Tyczkowska et al., 1994; Rantala et al., 2002). In another study, the concentrations of ciprofloxacin in milk of dairy cows exceed the plasma concentration by 45 times (Chiesa et al., 2013). Danofloxacin distribution into milk of cows also exceeded serum concentrations (Shem-Tov et al., 1998). In rabbits the milk-to-plasma ratios were 3.6 and 2.6 for enrofloxacin and ciprofloxacin, respectively, after administration of 7.5 mg/kg IV (Aramayona et al., 1996).

The high distribution of fluoroquinolones into milk is apparently caused by active transport by proteins in the udder. One of the transporters responsible is the breast cancer resistance protein (BCRP), an ATP-binding cassette transporter (Real et al., 2011). Protein binding is high in milk, which may also trap enrofloxacin and ciprofloxacin (Aramayona et al., 1996). Despite these concentrations of fluoroquinolones in milk, the activity of enrofloxacin in mastitic milk is decreased, possibly owing to lower pH, chelation with cations, or other factors in milk that inhibit fluoroquinolone activity (Kaartinen et al., 1995). Although an experimental study showed promising results for treating mastitis caused by *E. coli* (Rantala et al., 2002), clinical results have been more disappointing (Suojala et al., 2010). In the United States, this would be considered extralabel use and is prohibited.

When administering fluoroquinolones to nursing animals, the amount in the milk should be considered because fluoroquinolones may cause arthropathy in some species of young animals (discussed further in Section Safety). Disposition into milk was studied in two mares after administration, and it was shown that although both ciprofloxacin and enrofloxacin were present in milk at levels that were as high or higher than the mares' plasma concentrations, the total doses administered to the foals via suckling were small, and the plasma concentrations in the foals were negligible (author's observations). Likewise, when ciprofloxacin was administered to cows, the concentration in milk was high, and delivered an oral dose of 0.5 mg/kg to suckling calves (Chiesa et al., 2013). However, the drug did not accumulate in calves and concentrations in the calves were one-tenth to one-fifth the concentration in the cow. Young nursing animals may have decreased oral absorption caused by interference from calcium in milk (see information on kittens in Section Young Animals).

Pregnant Animals

When administering fluoroquinolones to pregnant animals, there will be some drug transfer across the placenta because these drugs are lipophilic and have low protein binding, and drug transfer is not limited by tissue barriers. Placental transfer has been specifically examined in rabbits, in which it was shown that the more lipophilic drug, enrofloxacin, crossed the placenta to a greater degree (80%) than ciprofloxacin (5% placental transfer), which is less lipophilic (Aramayona et al., 1994). Despite the rather high transfer of enrofloxacin across the placenta, there have been no reports of adverse effects when fluoroquinolones were administered to pregnant animals. Manufacturer studies have not shown any adverse effects on pregnancy or reproduction.

Young Animals

There is a risk that fluoroquinolones may cause damage to the developing cartilage of young animals. This is discussed more thoroughly in the Section Safety. There have been few pharmacokinetic comparisons of young animals versus older animals, but the studies available demonstrate that young animals were exposed to more drug than adults because of slower clearance. After administration of enrofloxacin, calves at 1 day of age had smaller volume of distirubion, longer half-life, and decreased clearance than at 1 week of age (Kaartinen et al., 1997). There also was a smaller amount of metabolism of enrofloxacin to ciprofloxacin in 1-week-old calves than in older ones. Rabbit pups exhibited lower clearance and longer half-life for enrofloxacin than adult rabbits (Aramayona et al., 1996). This pattern was also seen in horses: foals at 1–2 weeks of age showed little metabolism of enrofloxacin to ciprofloxacin after administration of IV and oral doses. Foals also exhibited slower clearance and longer half-life than adults (Bermingham et al., 2000).

In kittens, enrofloxacin was administered at 5 mg/kg via various routes (oral, IV, SC) (Seguin et al., 2004). There was no evidence of adverse effects or impaired excretion of enrofloxacin in kittens. The half-life in young cats (2, 6, and 8 weeks old) was shorter, and clearance more rapid, than in adult cats, Volume of distribution in 6 to 8-week-old cats was larger, and combined with the shorter half-life, produced lower plasma concentrations than in adults. Oral administration to kittens produced low plasma concentrations and it was hypothesized that interference with milk in nursing kittens may lower oral absorption (see Section Drug Interactions).

Safety

The fluoroquinolones have had a good safety record. For enrofloxacin, the LD_{50} in laboratory rats is 5000 mg/kg. When high doses were administered to animals during safety testing, one of the most common problems was gastrointestinal disturbances (nausea, vomiting, diarrhea), but these were usually produced at high doses and were not serious. Because most of these drugs used in animals do not alter the anaerobic flora of the gastrointestinal tract, there usually is minimal disruption of the intestinal bacterial population, even when these drugs are administered orally to rodents. There have been no reports of cutaneous drug reactions resulting from fluoroquinolone administration in the veterinary literature, but some of the freedom of information (FOI) summaries from manufacturers report an occasional reddening of the skin of dogs when high doses were administered.

There have been no reports of adverse effects on reproduction or pregnancy from administration of fluoroquinolones. Although the use in pregnant animals has been discouraged because of toxicity to developing cartilage, there have been no clinical reports where this effect has been described in offspring of treated animals.

After administration of high doses, adverse central nervous system (CNS) effects have been observed. The mechanism responsible for the CNS effects is probably through antagonism of the inhibitory neurotransmitter GABA. Fluoroquinolones injected rapidly IV or administered at high doses can induce CNS excitement. Fluoroquinolones can precipitate convulsions in some animals and these agents should be administgered cautiously to animals that are prone to seizures.

Safety issues have arisen in people that have been the subject of a warning by the FDA. On May 12, 2016, the FDA issued a warning to physicians advising that the serious side effects associated with fluoroquinolone antibacterial drugs generally outweigh the benefits for patients with sinusitis, bronchitis, and uncomplicated urinary tract infections who have other treatment options. For patients with these conditions, fluoroquinolones should be reserved for those who do not have alternative treatment options. During the FDA review, they revealed that fluoroquinolones when used systemically (i.e., tablets, capsules, and injectable) are associated with disabling and potentially permanent serious side effects. These side effects can involve the tendons, muscles, joints, nerves, and central nervous system. Some signs and symptoms of serious side effects include tendon, joint and muscle pain, a "pins and needles" tingling or pricking sensation, confusion, and hallucinations. Subsequently, the FDA is requiring sponsors to update their drug labels for all fluoroquinolone antibacterial drugs. The joint effects in young dogs and horses are discussed in Section Problems in Young Animals, but to our knowledge tendon injuries and the other concerns cited by the FDA for people have not been reported from the use of fluoroquinolones in animals.

Blindness in Cats

High doses of fluoroquinolones have caused ocular problems in cats from drug-induced changes in the retina (Corrado et al., 1987). This concern was precipitated by a report by Gelatt and colleagues (Gelatt et al., 2001) in which retinal degeneration was associated with enrofloxacin administration. This was followed by studies by the manufacturer in which toxicosis from enrofloxacin was described and new dose labeling was announced. The most common ophthalmological abnormalities were mydriasis, lack of menace reflex, and poor papillary light reflexes. Acute blindness may occur and retinal lesions were observed, which include increased tapetal reflectivity and attenuation of retinal blood vessels. In one review of safety studies (Corrado et al., 1987) nalidixic acid (one of the earlier quinolones) at 100 mg/kg/day, but not norfloxacin at 200 mg/kg/day produced both electrical and histopathological changes in feline retinas. In another review (Schluter, 1987), the author states that feline retinas are particularly sensitive to fluoroquinolones. When cats received 100 mg/kg of nalidixic acid there was suppression of electroretinographic waves and histological changes in the cones and rods, but ciprofloxacin treatment at the same dose to cats had no effect on the electroretinographic findings or on the fundus.

In studies performed by the manufacturer, enrofloxacin was administered to cats at doses of 0, 5, 20, and 50 mg/kg for 21 days (eight cats per group). There were no adverse effects observed in cats treated with 5 mg/kg/day of enrofloxacin. However, the administration of enrofloxacin at 20 mg/kg or greater caused salivation, vomiting, and depression. At doses of 20 mg/kg or greater, there were mild to severe fundic lesions on ophthalmological examination, including changes in the fundus and retinal degeneration. There was also abnormal electroretinograms, including blindness. Ford et al. (2007) reported on a study in 24 cats that received 3, 5, or 7 days of enrofloxacin at a high dose of 50 mg/kg (10 times the label dose). Ocular changes were observed by day 3 of the study. At this dose, enrofloxacin caused both retinal degeneration and systemic toxic effects. Because the blindness has been associated with high doses, the manufacturer has limited the dose to 5 mg/kg/day in cats.

The other fluoroquinolones approve for use in cats are orbifloxacin (Orbax), pradofloxacin (Veraflox), and marbofloxacin (Zeniquin). The current approved dose of orbifloxacin for cats is 2.5–7.5 mg/kg/day. In a published abstract (Kay-Mugford et al., 2001), orbifloxacin oral liquid was administered to cats at 0, 15, 45, and 75 mg/kg for at least 30 days (eight cats/group). This represents 6, 18, and 30 times the lowest label dosage. No ocular lesions were observed in any cats treated with 15 mg/kg. At the higher doses (18 and 30 times dose) there was tapetal hyperreflectivity in the area centralis and minimal photoreceptor degeneration. When marbofloxacin was administered to cats at 5.55, 16.7, and 28 mg/kg, representing 2, 6, and 10 times the lowest label dose, for 6 weeks, there were no ocular lesions in cats (manufacturer's data). At 55.5 mg/kg (10 times the lowest label dose) for 14 days there were also no lesions from marbofloxacin. As discussed above in the Section Pradofloxacin Use in Dogs and Cats, it has been administered safely to cats without producing ocular problems.

Problems in Young Animals

Fluoroquinolones can produce an arthropathy in young rapidly-growing animals (Gough et al., 1992; Burkhardt et al., 1997). The species most susceptible to developmental arthropathy are rats and dogs. Dogs between the ages of 4 and 28 weeks are the most susceptible. Affected dogs may show signs of lameness and joint swelling, but when the drug was discontinued, the lesions were reversible. Kittens, calves, and pigs are more resistant to this effect. For example, feeder calves and 23-day-old calves were administered 25 mg/kg for 15 days without evidence of articular cartilage lesions. Young foals are susceptible to the joint arthropathy from enrofloxacin at 10 mg/kg orally (Bermingham et al., 2000). However, studies in adult horses treated with enrofloxacin have not demonstrated articular toxicity (Bertone et al., 2000; Giguère et al., 1999).

The risk increases with higher doses and in most instances has been more clinically obvious only when the highest maximum dose was exceeded (e.g., at 25 mg/kg of enrofloxacin); however, even enrofloxacin dosages of 10 mg/kg/day have induced cartilage damage in young dogs. Lesions may occur in as few as 2 days after initiation of treatment (Yabe et al., 2001). The use of fluoroquinolones has been discouraged in children, but thousands of children have been treated with these drugs under a compassionate protocol with no reports of joint arthropathy.

Joint arthropathy is caused by toxicity to the chondrocyte that causes vesicles to form on the articular surface. The mechanism for damage to cartilage is via chelation of magnesium by the drug (Egerbacher et al., 2001). Magnesium is necessary for proper development of the cartilage matrix, especially in young, growing animals. Chelation of the magnesium results in a local magnesium deficiency leading to loss of proteoglycan in the articular cartilage. Studies in which magnesium was supplemented to decrease cartilage damage had equivocal results. (Magnesium added to the diet while oral drugs are administered would cause a chelation and significantly decrease oral absorption.)

Diseases or Conditions

There has been limited study of the disposition of fluoroquinolones in animals that have other conditions. In most of these instances, there were no changes in the drug's pharmacokinetics that would necessitate a change in dosage. Since the fluoroquinolones rely on both the kidneys and liver for clearance, insufficiency in one organ may result in compensation by the other clearance route. For example, renal failure may result in more reliance on hepatic clearance. In dogs with renal impairment, clearance of marbofloxacin was only slightly decreased and there was no significant effect on volume of distribution or mean residence time (Lefebvre et al., 1998). In camels deprived of water for 14 days and lost 12.5% of their body weight, there was little effect on the distribution, clearance, or half-life of enrofloxacin. However, water deprivation resulted in a slower and less complete absorption from a SC injection compared to normal camels or camels injected IM (Gavrielli et al., 1995).

Drug Interactions

Combinations with other antibiotics neither antagonize nor enhance the microbiological effects of fluoroquinolones. Fluoroquinolones will kill bacteria whether or not they are dividing (Lode et al., 1998). Therefore, use of a bacteriostatic agent should not interfere with the action of a fluoroquinolone. Although there is no evidence that other antibiotics produce a synergistic effect when administered with fluoroquinolones, they may broaden the spectrum of activity.

Fluoroquinolones are involved in some drug interactions, but few of these are serious. Drugs containing di- and trivalent cations (e.g., Ca^{2+}, Mg^{2+}, Al^{+3}, Fe^{+3}), such as antacids, sucralfate, and nutritional supplements, can inhibit oral absorption (Simon et al., 2010; Nix et al., 1989). The effect on oral absorption is caused by chelation of the di- and trivalent cations to the quinolone, which inhibits permeability through the intestine, and can also affect drug solubility in the intestine that is needed for absorption (Simon et al., 2010). Although these effects are well documented in people, especially for ciprofloxacin, the results have been inconsistent in animals. Sucralfate (containing Al^{+3}) did not decrease oral absorption of enrofloxacin in dogs, and ciprofloxacin absorption was so inconsistent that it was not possible to detect a statistically significant interaction (KuKanich et al., 2016).

Cations mixed with fluoroquinolones in extemporaneously compounded preparations, can chelate the drug and decrease oral absorption. Chelation occurs on the carboxyl group at the 3-carbon position (Figure 37.1). Fluoroquinolones may inhibit metabolism of some drugs through an interaction with hepatic metabolism. One such example is the inhibition of theophylline metabolism by enrofloxacin (Intorre et al., 1995), in which enrofloxacin significantly increased the peak concentration and decreased systemic clearance of theophylline in dogs. This interaction occurs because enrofloxacin inhibits the cytochrome P540 enzyme CYP 1A2 enzyme (Martinez et al., 2013). There are other substrates for this enzyme, but there have not been reports of studies to examine if other interactions are possible in animals.

Fluoroquinolone interactions with pharmacokinetics of some nonsteroidal antiinflammatory drugs (NSAIDs) have been observed in animals (Ogino et al., 2005; Sidhu et al., 2005). However the interaction is inconsistent. Enrofloxacin inhibited the clearance of flunixin, and vice versa (Ogino et al., 2005), but marbofloxacin increased the clearance of tolfenamic acid and decreased the concentrations (Sidhu et al., 2005). If a reaction with an NSAID is possible, it is likely because of competition for tubular secretion.

Formulations Available

Fluoroquinolones approved for small-animal use are available as oral preparations as tablets or chewable tablets. There are no oral liquid preparations currently available in the United States, but oral solutions are available in other countries (5 and 25 mg/ml). When oral liquid formulations have not been available, veterinarians have used compounding pharmacists to create oral liquid formulations from tablets dissolved in an aqueous vehicle (Petritz et al., 2013; Carpenter et al., 2009). There are two formulations of enrofloxacin, an IM injectable preparation for dogs (2.27% solution, 22.7 mg/ml), and an injectable for cattle (100 mg/ml). The solutions are not approved for IV administration, but veterinarians have occasionally administered this preparation IV. The IV administration has not produced serious problems, but one should avoid rapid IV injection; otherwise, CNS reactions are possible. In addition, mixing a solution with some intravenous solutions may cause chelation and precipitation in the IV line. Fluids of particular concern are those that contain calcium or magnesium. The formulation approved for SC injection in cattle in the United States is 100 mg/ml in an L-arginine base. This preparation may cause tissue irritation if injected in small animals. It is very alkaline and has produced oral mucosal lesions when used for oral administration to horses (Boeckh et al., 2001).

There is an otic preparation available (Baytril otic) containing 5 mg/ml enrofloxacin and 10 mg/ml silver sulfadiazine. Some veterinarians have also used topical administration of enrofloxacin for otitis externa caused by pseudomonads (Griffin, 1993, 1999; Rosychuk, 1994). Other otic preparations have been mixed extemporaneously by veterinarians, even though these are not approved or evaluated for efficacy. For example, veterinarians have mixed the 2.27% injectable solution of enrofloxacin with saline, water, or other topical ear solutions in a 1 : 1 to 4 : 1 ratio (e.g., 4 parts saline, 1 part enrofloxacin). Stability studies by the author (MGP) with HPLC analysis confirmed these solutions to be stable for 2 weeks at room temperature.

Danofloxacin mesylate (Advocin), available as 180 mg/ml (and in some countries 25 mg/ml), is used for administration to cattle, SC in the neck area. It has a 2-pyrrolidone and polyvinyl alcohol vehicle. Marbofloxacin (Zeniquin) is available in tablets for dogs and cats. There is an injectable formulation available in some countries for small animals, cattle, pigs, and horses (Marbocyl, Forcyl), but not in the United States. Orbifloxacin is available in tablet form for dogs and cats. There are many more formulations available around the world not listed here. For example, the European Medicines Agency web site (http://www.ema.europa.eu/ema/) lists 120 pages of fluoroquinolone formulations approved for animals in various countries. There is not enough space in this chapter to list all these formulations but a visit to the EMA web site, and the FDA approved drug web site (http://www.accessdata.fda.gov/scripts/animaldrugsatfda/).

Antifungal and Antiviral Drugs

Jennifer L. Davis and Lara Maxwell

Antifungal Drugs

The need for safe and effective antifungal drugs has become important, particularly in small-animal medicine, with the recognition of serious systemic fungal diseases as well as the need for effective drugs to treat skin infections caused by dermatophytes and yeasts. Some animals are at a greater risk of fungal infections because they have other diseases or received medications that can produce immunosuppression, including hyperadrenocorticism, cancer chemotherapeutics, radiation therapy, or prolonged courses of corticosteroids. Fortunately, there have been many advances in the development of antifungal drugs in the last 20 years. Effective oral drugs are more widely used and there are newer, safer formulations of injectable agents. Figure 38.1 illustrates the sites of drug action for common antifungal drugs used in veterinary medicine. Unfortunately, there are only a few antifungal drugs that are approved for veterinary species (notable exceptions are topical products). Therefore, veterinarians often administer human-label drugs in an extralabel manner to animals.

Griseofulvin

Griseofulvin (Fulvicin U/F®, Fulvicin P/G®, Grifulvin V®, Grisactin®, Grisactin ultra®), is a fungistatic antibiotic produced by *Penicillium griseofulvin dierckx*. It is colorless, slightly bitter, and virtually insoluble in water. There are two types of preparations, the microsized and the ultramicrosized. Due to increased surface area, the ultramicrosized formulations have almost 100% bioavailability, whereas oral absorption of microsized formulations is lower and more variable (25–70%). The ultramicrosized preparations are not used often in veterinary medicine because of the higher cost. If the ultramicrosized form is used, the dose must be decreased to account for differences in absorption.

Mechanism of Action

Griseofulvin's selective toxicity is based on an energy-dependent uptake into susceptible fungi that occurs preferentially in fungal cells rather than mammalian cells. Once inside the cell, griseofulvin disrupts the mitotic spindle by interacting with polymerized microtubules, thus causing mitotic arrest in metaphase. Grossly this may appear as shortened fungal hyphae that have fewer branching points. This is known as the *curling* phenomenon. Griseofulvin may also interfere with cytoplasmic tubule formation, thereby inhibiting normal cellular trafficking.

Spectrum of Activity

Griseofulvin's activity is limited to organisms causing dermatophytosis, *Microsporum* spp., *Trichophyton* spp., and *Epidermophyton*. Fungal resistance to griseofulvin, caused by decreased energy-dependent uptake into the fungal cell, has not been reported to be a clinically important problem in veterinary medicine until recently. A 2013 study of feline and canine dermatophytosis showed therapy with griseofulvin failed to achieve both mycological and clinical cure in 16 dogs (39%) and four cats (40%), with some *M. gypseum* isolates from these animals reaching MIC values of >150 μg/ml (Nardoni et al., 2013).

Pharmacokinetics

Pharmacokinetic properties were reviewed by Hill et al. (1995). Griseofulvin distributes to the keratin of skin, hair, and nails and can be detected in the stratum corneum within hours of administration. Because of low water solubility, griseofulvin absorption is enhanced when given with a meal with high fat content. Only a small fraction of the dose is present in other body fluids or tissues. Absorption is nonlinear, and increases in doses may lead to a decreased fraction absorbed, as the rate-limiting step for absorption shifts from dissolution to solubility (Tanaka et al., 2013). The plasma half-life in the dog is 47 minutes (Harris and Riegelman, 1969);

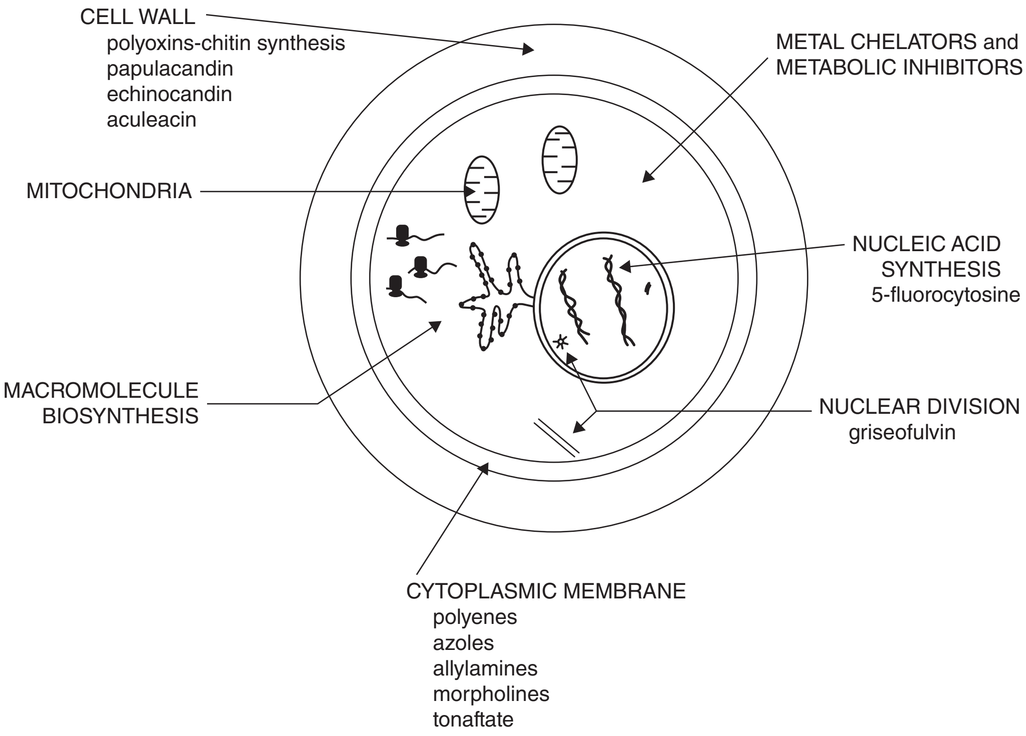

Figure 38.1 Schematic anatomy of a fungal cell and potential sites where antifungal drugs act.

however, the half-life at the site of action — the stratum corneum — is prolonged because the drug is bound tightly to keratinocytes and remains in the skin until these cells are shed. Thus, new hair or nail growth is first to become free of disease as keratin infected by fungus is replaced by new cells.

Griseofulvin is metabolized primarily by the liver to demethylgriseofulvin and the glucuronide. It is metabolized approximately six times faster in animals than in people, which is the reason animal doses are higher than human doses (half-life in dogs is less than 1 hour, compared to 20 hours in people) (Shah et al., 1972).

Clinical Use

Small animals: Griseofulvin is still used for treating dermatophytosis, but is being gradually replaced by azole drugs (discussed in Section Azole Antifungal Drugs). The recommended doses have varied, depending on the author. The label dose in dogs and cats for Fulvicin U/F® tablets is 11 to 22 mg/kg/day, but recommendations by specialists in dermatology have ranged from 44 mg/kg/day to 110–132 mg/kg/day in divided treatments (Scott, 1980). One review suggested a dose of 50 mg/kg once a day of the microsize formulation (Hill et al., 1995), and another review listed 25 mg/kg every 12 hours (deJaham et al., 2000), but the dose can be doubled for refractory cases. The most common dose is in the range of 50 mg/kg/day, which was confirmed in a report in which it was used in cats and was as effective as itraconazole for treatment of dermatophytosis (Moriello and DeBoer, 1995).

Griseofulvin is available in 125 and 250 mg capsules; 125, 250, and 500 mg tablets; and 125 mg/ml oral syrup. Often, at least 4 weeks are needed for successful therapy, and some patients require 3 months (or more) of continuous therapy. As long as 4 months may be necessary to treat infections of the nail bed (onychomycosis).

Large animals: Griseofulvin is approved at a dose of 2.5 g/day orally in adult horses for a minimum of 10 days. This translates to one packet of the powder formulation or one bolus per day, administered on feed. The dose for foals is half packet or half bolus per foal. Its use is limited to cases of dermatophytosis. There are currently no approved griseofulvin products for use in food animals in the United States. Nevertheless, when used off-label, griseofulvin has been effective in the prevention and treatment of dermatophytes in cattle (Reuss, 1978). Doses used are approximately 7.5–10 mg/kg for 7 to 35 days. At doses of 7.5 mg/kg orally once a day for 7 days, drug metabolites were still detectable in the liver of treated cattle at 10 days following the last administration (Tarbin and Fussell, 2013). A dose rate of 1 g/100 kg has been recommended for pigs for a duration of 30–40 days (Kielstein and Gottschalk, 1970). Because this drug is not approved, veterinarians must determine proper food animal withdrawal times for this drug prior to administration.

Adverse Effects

The most serious adverse effects associated with griseofulvin occur in cats and include leukopenia, anemia, increased hepatic enzyme activity, and neurotoxicosis (Helton et al., 1986). Ataxia in a kitten (Levy, 1991) and bone marrow hypoplasia in an 8-year-old cat (Rottman et al., 1991) have been reported. Prolonged treatment of eight cats with griseofulvin at the high end of the dosage range resulted in no untoward clinical, hematological, or hepatic side effects, suggesting that griseofulvin toxicity may be idiosyncratic (Kunkle and Meyer, 1987). Cats with feline immunodeficiency virus (FIV) appear to be at increased risk for griseofulvin-associated neutropenia (Shelton et al., 1990); however, toxicity has also been reported in FIV-negative cats (Rottman et al., 1991). The mechanism of this increased risk is unknown but may involve griseofulvin-enhanced binding of immune complexes to granulocytic cells in infected cats (Shelton et al., 1991).Griseofulvin should never be administered to pregnant cats. Its teratogenicity has been well-documented (Scott et al., 1975; Gruffydd-Jones and Wright, 1977). The teratogenic effects include cranial and skeletal malformations as well as ocular, intestinal, and cardiac problems (Scott et al., 1975). It has been given to pregnant horses with no apparent ill effect (Hiddleston, 1970); however, this may be dependent on the stage of pregnancy in which the drug was given. One report documented bilateral microphthalmia, brachygnathia superior, and palatocheiloschisis of the drug when given to a mare in the second month of pregnancy (Schutte and Van den Ingh, 1997). The labeled products for horses state not to administer to animals with impaired hepatic function.

Amphotericin B

Amphotericin B (Fungizone®, Abelcet®, Amphotec®, AmBisome®) is a polyene antibiotic with a large macrolide ring with a hydrophobic conjugated double-bond chain and a hydrophilic hydroxylated carbon chain and attached sugar (Figure 38.2) (Mechlinsk et al., 1970).

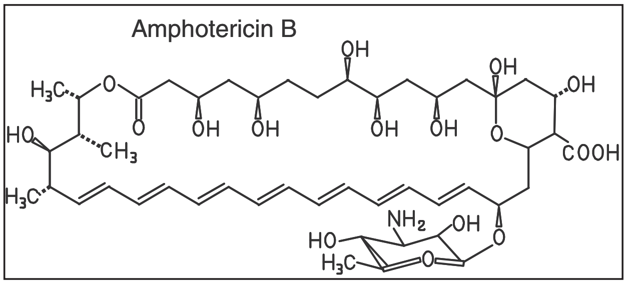

Figure 38.2 Amphotericin B.

It is a yellowish powder that is insoluble in water and somewhat unstable (Bennett, 1990). There are several formulations of amphotericin B available, including the conventional formulation, which is a micellar complex with the bile salt deoxycholate, and newer formulations that are lipid-based complexes. These are less toxic, but also more expensive (reviewed by Plotnick, 2000).

Amphotericin B lipid complex (Abelcet) is a suspension of amphotericin B complexed with two phospholipids. Amphotericin B cholesteryl sulfate complex (Amphotec, ABCD) is a colloidal dispersion of amphotericin B. The liposomal complex of amphotericin B (AmBisome) is a unilamellar liposomal formulation which, when reconstituted, produces small vesicles of encapsulated amphotericin B. Some investigators have attempted to achieve the benefits of lipid formulations without the added cost by mixing the deoxycholate salt in a 10 or 20% lipid solution (Intralipid). This formulation is stable for up to 3 weeks after mixing (Walker et al., 1998); however, the reports of the benefit of this emulsion versus the conventional formulation are inconsistent.

In comparison to the conventional formulation of amphotericin B, lipid formulations can be administered at higher doses to produce greater efficacy with less toxicity (Hiemenz and Walsh, 1996). Decreased toxicity is attributed to a selective transfer of the lipid complex amphotericin B, releasing the drug directly to the fungal cell membrane and sparing the mammalian cell membranes. Reduced drug concentrations in the kidneys and diminished release of inflammatory cytokines from amphotericin lipid complex compared to the conventional formulation may also prevent adverse reactions.

Mechanism of Action

The major action of amphotericin B is to bind ergosterol in the fungal plasma cell membrane, making the membrane more permeable and resulting in leakage of cell electrolytes and cell death (Brajtburg et al., 1990). At high concentrations, amphotericin B is thought to cause oxidative damage to the fungal cell (Warnock, 1991) or disruption of fungal cell enzymes. The selective toxicity of amphotericin B is based on its decreased binding to the major cell membrane sterol of mammalian cells (cholesterol) as compared to that of fungal cells (ergosterol).

Amphotericin B demonstrates concentration-dependent fungicidal activity. There is also a postfungal effect whereby an antifungal effect persists after drug concentrations have declined. This property allows for intermittent therapy (e.g., every other day in dogs).

Spectrum of Activity

The growth of strains of most veterinary fungal pathogens is inhibited in vitro at amphotericin B concentrations between 0.05 and 1.0 μg/ml and there is good correlation between the MIC values and clinical response (O'Day et al., 1987). Because of concentration-dependent killing, peak (C_{max}) concentrations should be two to four times above the MIC (C_{max}/MIC ratio of 2–4 : 1) (Goodwin and Drew, 2008).

Susceptible fungi include *Histoplasma capsulatum, Cryptococcus neoformans, Coccidioides immitis, Blastomyces dermatitidis, Candida* spp., and various species of *Aspergillus*. Amphotericin B has been indicated for treatment of mucormycosis, sporotrichosis, and phycomycosis (Drouhet and Dupont, 1987). Most strains of *Pseudallescheria boydii,* as well as some agents causing chromoblastomycosis and phaeohyphomycosis, are resistant to amphotericin. Clinical fungal resistance to amphotericin B, either primary or acquired, does not appear to occur commonly, although resistant strains occur in vitro. In most cases, these resistant strains contain decreased levels of membrane ergosterol (Pierce et al., 1978) and increased catalase levels may allow these fungi to be resistant to oxidative damage (Sokol-Anderson et al., 1988). The MIC concentrations were increased in some human patient populations, such as neutropenic patients (Dick et al., 1980), transplant patients (Powderly et al., 1988), and patients undergoing cytotoxic therapy.

The spectrum of activity also includes the protozoa *Leishmania* and is often included in protocols to treat human and canine leishmaniasis. The treatment of protozoa is discussed in Chapter 42.

Pharmacokinetics

Despite its long history of use, much is still unknown concerning the pharmacokinetics of amphotericin B, especially in veterinary medicine. It is poorly absorbed from the gastrointestinal (GI) tract and therefore must be given intravenously, locally, or intrathecally. Amphotericin B binds extensively (~95%) to serum proteins, mainly β-lipoprotein (Bennett, 1977). Much of the drug is thought to leave the vascular space and bind to cholesterol-containing membranes. The highest concentrations are found in liver, spleen, kidney, and lungs, with little accumulation in either muscle or adipose tissue. Concentrations of amphotericin B in fluids from inflamed pleura, peritoneum, synovium, and aqueous humor are about two-thirds of those in serum. Amphotericin B readily crosses the human placenta. Penetration into normal or inflamed meninges, vitreous humor, and normal amniotic fluid is poor. This differential distribution may explain treatment failures for infections in some tissues. Although amphotericin B binds ergosterol with higher affinity than cholesterol, it was suggested that because there are more binding sites for cholesterol in the body than for ergosterol, amphotericin B may be sequestered from its site of action (Bennett, 1977).

Clinical Use

Amphotericin B is used to treat a variety of fungal diseases caused by susceptible fungi, as listed above. Numerous dosage protocols for amphotericin B have been described in the veterinary literature. These are summarized in Table 38.1. One such protocol for small animals was published by Rubin (1986) that is still used today. During infusion, it should be mixed with 5% dextrose solution because it will precipitate if added to an electrolyte containing solution (e.g., lactated Ringer's solution). A solution of amphotericin B with 0.45% saline and 2.5% dextrose has been used successfully subcutaneously without any visible precipitation (Malik et al., 1996).

Amphotericin B is used only sporadically as a systemic antifungal in equine medicine and there are no pharmacokinetic data available on amphotericin in the horse. It is more often used as a local treatment in the eye, limbs, and upper airway. In cases of ocular fungal disease that do not respond to typical therapy, amphotericin B (0.2 ml of a 5 mg/ml solution) injected subconjunctivally q 48 h for up to three treatments can be used. This should provide a higher level of drug to the eye; however, it may produce localized toxic effects, including conjunctivitis and conjunctival necrosis. Intravenous regional limb perfusion (IRLP) has also been reported to successfully treat pythiosis of the lower limbs at a dose of 50 mg for one to two treatments (Dória et al., 2012). Side effects include limb edema with pain on palpation, and inflammation of the injection site; however, these signs are considered manageable and resolve after 14 days. Topical and intralesional therapy with amphotericin B has also been reported as a successful treatment for nasal conidiobolomycosis in the horse (French et al., 1985; Zamos et al., 1996). There are no reports of use of this drug in food animals, and there are no approved formulations for use in these species.

Combination therapy using amphotericin B and flucytosine has been shown to be synergistic against cryptococcal infections (see Section Flucytosine). Combinations of amphotericin B and azole antifungals have been less successful. Azole-induced depletion of fungal cell membrane ergosterol results in fewer binding sites on which polyene antifungals can exert their effect. Antagonism and synergism between these two classes of antifungal agents have been reported experimentally (Polak et al., 1982; Dupont and Drouhet, 1979). Because of the slower onset of action of azole antifungals, many clinicians recommend initial therapy of serious systemic fungal infections with amphotericin B, followed by longer, follow-up treatment with an azole therapeutic protocol.

Adverse Effects

The most important clinical toxicosis associated with amphotericin B therapy is nephrotoxicity. It is this effect

Table 38.1 Selected dosing protocols for amphotericin B in companion animals

Species	Formulation	Disease treated	Dosing protocol	Reference
Canine	Fungizone	Unspecified	Pretreatment with 0.9% sodium chloride followed by infusion of 0.5 mg/kg in 5% dextrose (D5W) over 4–6 hours IV q48h; a test dose of 0.25 mg/kg is sometimes recommended.	Rubin, 1986
Canine	Abelcet	Blastomycosis	Pretreatment with LRS at 2.5 times maintenance for 30 minutes followed by flushing the line with D5W and infusing 1 mg/kg amphotericin in D5W over 2.5 hours IV followed by LRS at 2.5 times maintenance for an additional 2 hours after treatment. Repeat q48h to a total cumulative dose of 8–12 mg/kg.	Krawiec et al., 1996
Canine	Abelcet	Unspecified	2–3 mg/kg IV 3 times per week diluted in 5% dextrose to a concentration of 1 mg/ml for a total of 9–12 treatments (cumulative dose of 24–27 mg/kg).	Grooters and Taboada, 2003
Canine	AmBisome	Leishmaniasis	3–3.3 mg/kg IV.	Oliva et al., 1995
Canine	Fungizone 40 ml sterile water and 10 ml 10% Intralipid	Leishmaniasis	Pretreatment with 50 ml/kg of 0.9% sodium chloride followed by 10 ml/kg 20% mannitol. Drug mixture infused over 30–60 minutes at incrementally increasing dosing from 1–2.5 mg/kg IV twice a week for a minimum of 8 injections.	Lamothe, 2001
Canine/feline	Fungizone in 0.45% saline with 2.5% dextrose	Cryptococcosis	0.5–0.8 mg/kg SC in 400 ml for cats or 500 ml in dogs given twice a week for a cumulative dose of 8–26 mg/kg.	Malik et al., 1996
Feline	Abelcet	Unspecified	1 mg/kg IV 3 times per week diluted in 5% dextrose to a concentration of 1 mg/ml for a total of 12 treatments (cumulative dose of 12 mg/kg).	Grooters and Taboada, 2003
Equine	Fungizone	Phycomycosis	0.38 gradually increased up to 1.47 mg/kg IV in 1 l 5% dextrose once daily.	McMullan et al., 1977
Equine	Fungizone	Pulmonary histoplasmosis	0.3–0.6 mg/kg IV in 1 l 5% dextrose once a day or every other day.	Cornick, 1990
Equine	Fungizone	Systemic candidiasis	0.1–0.5 mg/kg IV in 1 l 5% dextrose infused over 4–6 hours once daily.	Reilly and Palmer, 1994
Equine	Fungizone	Candida arthritis	0.33–0.89 mg/kg IV in 1 l 5% dextrose once a day or every other day.	Madison et al., 1995
Equine	Fungizone	Cryptococcal pneumonia	0.5 mg/kg IV in 1 l 5% dextrose as a 1-hour infusion once a day.	Begg et al., 2004
Avian	Fungizone	Aspergillosis	1.5 mg/kg q8–12h reconstituted in sterile water and then diluted 1 : 50 with 5% dextrose for 3–7 days.	Tully, 2000

on kidneys that is the most common reason for discontinuing therapy with amphotericin B. It is a dose-related, predictable toxic effect that occurs in almost every animal treated with the conventional formulation. Direct tubular damage occurs because amphotericin B binds to cholesterol in the tubular cells, which results in electrolyte leakage from the cells (primarily K^+ loss) and renal tubular acidosis (Bennett, 1990). Induced renal vasoconstriction and impaired acid excretion may also contribute to amphotericin B's renal toxicity (Greene, 1990). Renal vasoconstriction may be caused by induced increases in the eicosanoid synthesis in renal blood vessels. The tubular damage, along with the renal vasoconstriction, leads to both an acute and a chronic cumulative renal toxicosis. Clinically, the signs of kidney injury are seen as increases in creatinine and blood urea nitrogen (BUN). Electrolyte loading, fluid diuresis, and slow infusion of amphotericin B have all been shown to decrease the severity and the rate of development of renal toxicity. Therefore, common protocols for administration of amphotericin B to animals include pretreatment with sodium chloride IV solution (Rubin, 1986) with or without mannitol (Legendre et al., 1984), and a slow infusion. Slower infusion times are associated with less kidney injury (Rubin, 1986). If the dose administered during a single infusion exceeds 1 mg/kg, acute renal injury is likely (Butler and Hill, 1964).

Careful clinical monitoring will help decrease the risk of permanent renal injury. Urine sediment evaluation has been suggested to detect kidney injury earlier than serum biochemical alterations (Greene, 1990); thus, urine should be evaluated for proteinuria, cylinduria, and hematuria, as well as specific gravity. In addition, BUN, creatinine, and electrolyte concentrations should be monitored. Therapy should be temporarily discontinued when active urine sediment is detected or the serum creatinine increases. After stopping therapy, patients may undergo a fluid diuresis to decrease the azotemia. If BUN and creatinine return to near-normal reference values, treatment may be resumed. If azotemia does not improve, one should consider an alternative treatment.

Other adverse effects from amphotericin that are frequently observed in animals include phlebitis, fever, nausea, and vomiting. Measures to prevent the nausea and vomiting have included administration of antiemetic drugs such as chlorpromazine, maropitant, or metoclopramide prior to infusion (see Chapter 46). Hypokalemia, bronchospasm, and anemia/hemolysis have frequently been reported in humans and therefore should be monitored for in veterinary patients.

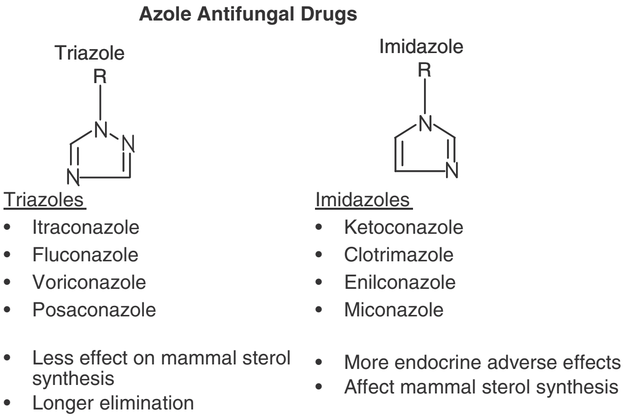

Figure 38.3 Azole antifungal drugs

Azole Antifungal Drugs

The azole antifungal drugs have a high safety profile, a broad spectrum of activity, and are available in topical, oral, and intravenous formulations. There are two main categories of azole antifungal drugs, the imidazoles (clotrimazole, miconazole, ketoconazole) and the triazoles (fluconazole, itraconazole, voriconazole) (Figure 38.3). Clotrimazole and miconazole are discussed in the section on topical therapy. The important physicochemical differences between azole antifungal drugs are summarized in Table 38.2.

Mechanism of Action

All azoles exert their antifungal effect on the cell membrane of fungi by inhibiting synthesis of the primary sterol of the fungal cell membrane, ergosterol. Inhibition of the P450–dependent lanosterol C_{14}-demethylase enzyme results in depletion of ergosterol and

Table 38.2 Comparison of the physicochemical properties and in vitro activity of commonly used azole antifungal drugs

					Activity		
Drug	**Solubility**	**pH Dependent**	**LogP**	**Protein binding**	**Yeasts**	**Aspergillus**	**Fusarium**
Ketoconazole	pi	Yes	3.78	>90%	+	±	−
Fluconazole	ss	No	0.54	10–12%	+	−	−
Itraconazole	pi	Yes	5.66	>98%	+	±	−
Voriconazole	vss	No	1.81	32–58%	+	+	±

pi, practically insoluble (<0.01 mg/ml); ss, slightly soluble (1–10 mg/ml); vss, very slightly soluble (0–1 mg/ml).

accumulation of C_{14}-methyl sterols in the cytoplasmic membrane of yeasts and filamentous fungi. This enzyme is also known as CYP51A or Erg11p and is encoded by the *ERG11* gene. Inhibition of this cytochrome P450 enzyme occurs via binding of the nitrogen (N_3 of imidazoles and N_4 of triazoles) to the heme iron atom of ferric cytochrome P450. This prevents the formation of the superoxide Fe^{+3} complex ($Fe^{+3}O^-$) needed for hydroxylation of methyl sterols. The result is an inability to demethylate C_{14}-methyl sterols and reduced synthesis of ergosterol. Sterols with less planar configurations are then incorporated into the fungal cell wall, which changes membrane fluidity and interferes with the barrier function of the membrane and with membrane-bound enzymes.

Azole drugs are generally fungistatic at concentrations achieved clinically, although there are exceptions for some fungal species, and for some drugs. The parameter that is best associated with clinical cure for azole drugs is the total exposure as measured by the area-under-the-curve in relation to the MIC (AUC/MIC ratio) (Goodwin and Drew, 2008).

The potency of each azole drug is related to its affinity for binding the P450 enzyme. The selective toxicity of each compound is directly dependent upon its specificity for binding fungal P450 more readily than mammalian P450. Imidazoles are less specific than triazoles and produce side effects in animals attributed to inhibition of P450 enzymes that are responsible for the synthesis of cortisol and reproductive steroid hormones. Azoles may decrease cholesterol, cortisol, androgen, and testosterone biosynthesis and may interfere with hepatic CYP450 enzymes that are important for drug metabolism and carcinogenic agents (Polak, 1990). These drugs also may inhibit the membrane transporter known as P-glycoprotein.

Interactions with Drug Metabolism

The inhibition of mammalian P450 enzymes is also responsible for drug–drug interactions that have been observed with the azole antifungals. When azoles are administered concurrently with other drugs that are metabolized by these enzymes, they can significantly increase the plasma concentrations of those drugs. Alternatively, when azoles are administered concurrently with drugs that induce the P450 enzymes, the concentrations of the azole drugs may be significantly decreased. The drug–drug interactions important to veterinary medicine are summarized in Table 38.3. The ability to inhibit mammalian P450 enzymes, and therefore the likelihood of drug–drug interactions, is greatest with ketoconazole (Aidasani et al., 2008) followed by itraconazole, voriconazole, and fluconazole.

Another method by which the azole antifungals can interfere with the absorption and pharmacokinetics of concurrently administered medications is through inhibition of the P-glycoprotein efflux pumps. These efflux pumps can be found in the intestine, where they limit the absorption of some substrates, as well as in the liver, kidney, eye, and CNS. At the intestinal level, there is a relationship between the P-glycoprotein efflux pump and the metabolism by intestinal CYP450 enzymes (Benet, 2009). Inhibition of both can have profound effects on systemic drug concentrations. Azole antifungals have the ability to inhibit P-glycoprotein pumps and therefore increase the oral absorption and tissue distribution of drugs within the body, particularly into protected sites, such as the blood–brain barrier and the blood–retinal barrier. The ability to inhibit P-glycoprotein is greatest with itraconazole, followed by ketoconazole and voriconazole (Wang et al., 2002). Fluconazole has little interaction with P-glycoprotein, which may explain why it has fewer significant drug interactions compared to the other azole antifungals (Yasuda et al., 2002; Wang et al., 2002).

Ketoconazole

Ketoconazole (Nizoral®), one of the imidazoles, became available in 1979. The results of successful use in veterinary medicine were published shortly thereafter (Legendre et al., 1982; Medleau et al., 1985). Ketoconazole is available in 200 mg tablets, and generic formulations are inexpensive and readily available.

Spectrum of Activity

Ketoconazole is most effective against yeast and dimorphic fungi such as *Candida*, *Malassezia pachydermatis*, *C. immitis*, *H. capsulatum*, and *B. dermatitidis*, as well as most dermatophytes with MIC values less than 0.5 μg/ml. It is less effective against *C. neoformans*, *S. schenckii*, and *Aspergillus* spp., with MIC values varying from 6 to >100 μg/ml (Hume and Kerkering, 1983).

Pharmacokinetics

Ketoconazole is relatively insoluble, except in an acid environment. It is not well absorbed orally unless there is acid secretion, such as after a meal. Ketoconazole is highly protein bound (>98%) and therefore does not penetrate into the cerebrospinal, seminal, or ocular fluid to a significant degree; although it does partition into milk. It distributes throughout the skin and subcutaneous tissue, making it effective for treatment of superficial and systemic fungal skin infections. The drug demonstrates nonlinear absorption and elimination kinetics, most probably due to saturation of solubility or metabolizing enzymes. It is biotransformed in the liver via O-dealkylation and aromatic hydroxylation and excreted mainly in the bile. Elimination half-life is approximately 2 hours in dogs.

Because ketoconazole is soluble only in acid aqueous environments (pH <3), gastric alkalizing agents (e.g.,

Table 38.3 Antifungal drug–drug interactions of significance in veterinary medicine[a]

	Drug/drug class	Result
Griseofulvin	Anticoagulants/coumarin or inandione derivatives	Griseofulvin is a hepatic enzyme inducer, which may increase the metabolism of these drugs, resulting in decreased anticoagulant effects.
	Barbiturates	Impaired absorption and therefore possibly impaired effectiveness of griseofulvin.
Amphotericin B	Bone marrow depressants	Increased risk of anemia or other blood dyscrasia.
	Corticosteroids	Exacerbation of hypokalemia, particularly with those drugs that have significant mineralocorticoid activity.
	Digoxin	Hypokalemia caused by AmpB increases the potential for digitalis toxicity.
	Neuromuscular blocking agents	Hypokalemia caused by AmpB enhances the blockade of nondepolarizing agents.
	Diuretics	Potassium depleting diuretics will exacerbate hypokalemia.
	Flucytosine	Synergism of AmpB with flucytosine may decrease the dose of AmpB necessary, therefore reducing the nephrotoxicity, however AmpB-induced renal dysfunction may increase 5-FC concentrations, thus increasing the potential for blood dyscrasias.
Azole Antifungals	Drugs that increase gastric pH	Decreases the absorption of those drugs with a pH-dependent solubility (ketoconazole and itraconazole only).
	Digoxin	Increased plasma concentrations of digoxin resulting from P450 inhibition may lead to increased digitalis toxicity.
	Benzodiazepines	Increased plasma concentrations of benzodiazepines, particularly midazolam, resulting from P450 inhibition may result in potentiation of the sedative effects of these drugs.
	Glipizide	Increased plasma concentrations of glipizide resulting from P450 inhibition may cause hypoglycemia.
	Second-generation antihistamines	Although identified in people, and not animals, there may be increased plasma concentrations of antihistamines resulting from P450 inhibition, which may result in cardiac arrhythmias, including ventricular tachycardia and torsades de pointes; not seen with fluconazole except at very high doses.
	Warfarin	Increased plasma concentrations of warfarin resulting from P450 inhibition may cause increased anticoagulant effects and bleeding.
	Cisapride	Although identified in people, and not animals, there may be increased plasma concentrations of cisapride resulting from P450 inhibition, which may result in ventricular arrhythmias, including torsades de pointes.
	Cyclosporine	Increased plasma concentrations of cyclosporine resulting from P450/P-gp inhibition may require adjustment of cyclosporine doses; has been used clinically to decrease the cost of cyclosporine treatment.
	Quinidine	Increased plasma concentrations of quinidine resulting from P450/P-gp inhibition may lead to increased quinidine toxicity.
	Nifedipine	Increased plasma concentrations of nifedipine resulting from P450/P-gp inhibition.
	Hydrochlorthiazide	Hydrochlorthiazide decreases the renal elimination of fluconazole, resulting in increases of fluconazole plasma concentrations.
	Carbemazapine	Induction of P450 enzymes by carbemazapine may decrease the plasma concentrations of antifungal drugs.
	Rifampin	Induction of P450 enzymes by rifampin may decrease the plasma concentrations of antifungal drugs.
	Phenytoin	Induction of P450 enzymes by phenytoin may decrease the plasma concentrations of antifungal drugs.
	Phenobarbital	Induction of P450 enzymes by phenobarbital may decrease the plasma concentrations of antifungal drugs.
	Prednisolone	Down-regulation of intestinal P-glycoprotein results in a subsequent increase in the AUC of orally administered prednisolone.
	Methadone	Inhibition of P450 enzymes results in significantly increased AUC and plasma concentrations of methadone after oral administration to healthy Greyhound dogs.
	Colchicine	Increased risk of colchicine toxicity when coadministered with azole antifungals.
	Other azole antifungals	Ketoconazole inhibits its own elimination, resulting in possible increased plasma concentrations over time.
Flucytosine	Bone marrow depressants	May exacerbate bone marrow toxicities.
	Nephrotoxic agents	May decrease flucytosine clearance, increasing the potential for bone marrow toxicity.
Terbinafine	*There are no reported drug–drug interactions with terbinafine.*	

[a] Not all of these interactions have been documented in veterinary medicine, but are present in human medicine and should be monitored for in veterinary patients.

antacids, H_2 blockers, and parietal cell proton pump inhibitors) or diseases resulting in achlorhydria will decrease its dissolution and oral absorption. Because of lack of consistent gastric acidity, ketoconazole is absorbed poorly in horses. When ketoconazole was administered at 30 mg/kg to horses in corn syrup, the drug was not detected in serum; however, when it was administered with 0.2 N hydrochloric acid intragastrically, oral absorption increased but systemic availability was only 23% with peak serum concentrations of 3.76 μg/ml (Prades et al., 1989).

Clinical Use

In people, ketoconazole has been replaced in therapy by safer triazole antifungal drugs and is no longer marketed in some countries. But in veterinary medicine, owing to ketoconazole's efficacy, safety, cost, and ease of administration, it is still a popular antifungal agent. For dermatophytosis in cats, 10 mg/kg/day has been used (Medleau and Chalmers, 1992). For candidiasis, 10 mg/kg/day for 6–8 weeks is recommended. For canine blastomycosis, histoplasmosis, cryptococcosis, and coccidioidomycosis, the dosage is 10–20 mg/kg every 12 hours. Ketoconazole may also be effective in treating nasal cryptococcosis in a dog at a dose of 10 mg/kg/day (Noxon et al., 1986). For *Malassezia* dermatitis in dogs, dosages of 5–10 mg/kg/day have been recommended (Hill et al., 1995). The duration of treatment is highly variable. Four to six weeks is a minimum for most diseases; many patients with blastomycosis are treated for a minimum of 2 months and as long as 6 months. If there is CNS involvement, particularly with cryptococcosis, higher doses (40 mg/kg) may be necessary to improve penetration into the CNS. Cats have been successfully treated for cryptococcosis with a dosage of 10–15 mg/kg/day (Pentlarge and Martin, 1986; Legendre et al., 1982; Medleau et al., 1985). As complete eradication of the fungal organism is difficult, relapse is common. For this reason, infections should be treated beyond the time clinical signs have resolved. Ketoconazole is not absorbed well orally in horses and it is not recommended. There are no approved formulations for use in food animals.

The use of ketoconazole is not limited to the treatment of fungal infections. Because of its inhibitory effect on P450 and P-glycoprotein, administration of ketoconazole concurrently with cyclosporine for the treatment of immune diseases has been used to reduce the dose of cyclosporine by up to 75% and reduce the cost of cyclosporine therapy by 58% (Dahlinger et al., 1998). A study examining blood and skin concentrations of cyclosporine with concurrent administration of ketoconazole at 2.5 mg/kg each showed this regimen to be potentially as effective as cyclosporine alone at 5.0 mg/kg for treatment of canine atopic dermatitis (Gray et al., 2013). Although this may be the most common interaction manipulated for clinical use, other drug–drug interactions have been reported. Ketoconazole (100 mg/day) administered to healthy beagle dogs resulted in down-regulation of intestinal P-glycoprotein and a subsequent increase in the AUC of orally administered prednisolone (Van der Heyden et al., 2012). Concurrent administration of ketoconazole with methadone significantly increased the AUC and plasma concentrations of methadone after oral administration to healthy Greyhound dogs (Kukanich et al., 2011). Other studies have shown that ketoconazole inhibits its own elimination, as well as that of midazolam in healthy Greyhounds, without any significant effect on fentanyl or morphine elimination (Kukanich and Hubin, 2010; Kukanich and Borum, 2008). Colchicine toxicity has also been reported to be precipitated by ketoconazole in a dog, and these drugs are not recommended for coadministration (McAlister et al., 2014).

Ketoconazole inhibits the synthesis of steroid hormones (via inhibition of the cytochrome P450 enzymes), most notably cortisol and testosterone. Although this may be a side effect of therapy, it has been exploited for the temporary management of hyperadrenocorticism in dogs (Bruyette and Feldman, 1988; Feldman et al., 1990) and as an antiandrogen treatment. Steroid synthesis inhibition is a temporary effect that persists only during dosing with ketoconazole (e.g., for up to 8 hours). Although the effects are temporary, they are effective. A recent retrospective study showed that ketoconazole administration improved clinical signs of hyperadrenocorticism in 90% of treated dogs, and 69% of dogs had cortisol concentrations following adrenocorticotropic hormone (ACTH) stimulation that were within the normal range (Lien and Huang, 2008). Dogs in that study were treated for the remainder of their life, with a median survival time after diagnosis of 25 months. Ketoconazole will not produce permanent hypoadrenocorticism.

Adverse Effects

Nausea, anorexia, and vomiting are the most common adverse effects, and may require cessation of therapy, particularly in cats (Medleau and Chalmers, 1992). They are usually dose related and may be diminished by decreasing the dose, dividing the total dose into smaller doses, and administering each dose with food. With chronic therapy pruritus, alopecia, lightening and drying of the hair coat, and weight loss may occur (Greene, 1990). Slight to moderate elevations of inducible hepatic enzymes are expected and may not be accompanied by hepatic injury. However, high elevations in hepatic enzymes, accompanied by other parameters (hyperbilirubinemia and clinical signs consistent with hepatic disease), may indicate hepatotoxicosis. Idiosyncratic hepatitis has been reported in animals and people (Janssen and Symoens, 1983).

Drug Interactions

Ketoconazole is a very potent inhibitor of fungal P450, but it also inhibits mammalian P450 at relatively low concentrations (Aidasani et al., 2008); therefore, side effects and drug interactions can occur. Inhibition of P450(17α) catalyzed conversion of progestins to androgens occurs during treatment. Dose-related inhibition of testosterone has resulted in gynecomastia, sexual impotence, and azoospermia. Cats appear to be more sensitive to ketoconazole liver toxicity than are dogs but they are less sensitive to the hormonal suppressive side effects (Willard et al., 1986a, 1986b).

Ketoconazole has been shown to be teratogenic in the rat and has resulted in mummified fetuses and stillbirths in dogs. It is therefore not recommended for use in pregnant or lactating animals. Cataracts have been reported after long-term ketoconazole therapy in dogs (de Costa et al., 1996). The average duration of therapy in affected dogs was 15 months, and dosages ranged from 6 to 31 mg/kg/day. These dogs were not diabetic. The mechanism of this reaction is not known.

Fluconazole

Fluconazole (Diflucan® and generic) has replaced ketoconazole in small animals and birds for many indications. The triazole groups result in increased resistance to metabolic attack, in vivo potencies 100 times that of ketoconazole, and significantly increased aqueous solubility (8 mg/ml) (Richardson et al., 1990). Because of these properties, this compound has good efficacy in animal models and pharmacokinetic properties that are improved over other azole antifungal drugs such as ketoconazole or itraconazole. It is available in 50–200 mg tablets, powder for oral suspension, and a 2 mg/ml parenteral formulation. Compounded formulations have good oral bioavailability and can be used with a reasonable expectation of performance.

Spectrum of Activity

Fluconazole has been shown to be effective for animal infections caused by *Blastomyces, Candida, Coccidioides, Cryptococcus*, and *Histoplasma*. It is not particularly active against *Aspergillus*. Resistant *Aspergillus* strains have been increasing in human medicine with MICs often >256 μg/ml. For this reason, fluconazole should not be used as a first choice for the treatment of aspergillosis unless susceptibility has been determined. Efficacy of fluconazole in people has been associated with AUC/MIC ratios as being the best predictor of cures. A ratio above 25 is considered desirable for the best outcome (Goodwin and Drew, 2008).

Pharmacokinetics

Fluconazole has different solubility characteristics than ketoconazole and itraconazole and is absorbed well regardless of the circumstances. Feeding or formulation (liquid versus tablet) does not affect absorption. Fluconazole demonstrates linear absorption kinetics, with bioavailability greater than 90% in most species (Brammer et al., 1990); thus, oral and IV dosages are identical. Maximum fluconazole concentrations are reached 1–4 hours after an oral dose. Unlike other azole antifungals, fluconazole is not highly protein bound. Humphrey et al. (1985) found plasma protein binding to be between 10 and 12% at concentrations of 0.1 and 1 μg/ml in mice, rats, dogs, and humans. Similar protein binding has also been documented in horses (12.3%) at a concentration of 5 μg/ml. Fluconazole's low molecular weight, water solubility, and high unbound fraction allow it to be readily distributed throughout the body, including privileged spaces that ordinarily exclude many drugs. Drug concentrations in saliva, sputum, skin, nails, blister fluid, and vaginal tissue and secretions were found to be similar to plasma concentrations. The advantages of fluconazole lie in its ability to produce higher CSF concentrations than ketoconazole or itraconazole; therefore, it may be useful for treating mycotic meningitis (Kowalsky and Dixon, 1991). Fluconazole CSF/plasma or CSF/serum concentration ratios range from 0.49 in horses (Latimer et al., 2001) to 0.88 in cats (Vaden et al., 1997). The drug also penetrates well into the aqueous humor with ratios of aqueous : plasma of 0.37 and 0.79 in the horse and cat, respectively.

Fluconazole is eliminated principally by the kidney. A unique feature of fluconazole is that this drug is the only one of the azoles that is water soluble and excreted in the urine in an active form; therefore, it may be one of the few drugs useful for treating fungal cystitis. As can be expected with a renally excreted drug, renal dysfunction affects fluconazole's elimination such that dose adjustments are necessary. When patients with normal kidney function were compared with those with severe renal insufficiency, fluconazole's elimination half-life nearly tripled (from 30.1 hours to 84.5 hours) (Dudley, 1990). Reduced dosages as well as extended dosing intervals have been recommended for patients with chronic kidney disease. The disparity between renal fluconazole clearance and creatinine clearance suggests that net tubular reabsorption is responsible for the extended half-life. Half-life was measured to be approximately 14 hours in dogs, 13–25 hours in cats (Vaden et al., 1997; Craig et al., 1994), and 38 hours in horses (Latimer et al., 2001). Steady-state concentrations are achieved in 5–7 days; thus, the manufacturer suggests a two-times loading dose during the first 12–24 hours (Dudley, 1990). The lack of significant hepatic metabolism allows for linear elimination kinetics; that is half-life is independent of dose.

Clinical Use

Small animals: Fluconazole is most often used for treatment of dermatophytes. Although not as active against

Aspergillus or *Penicillium* as other azoles, it has also been used to treat canine nasal aspergillosis and penicilliosis. Ten affected dogs were treated with 2.5–5 mg/kg/day fluconazole orally for 8 weeks. Six dogs became free of disease 2–4 weeks after cessation of therapy and remained free of disease for at least 6 months. Serum alkaline phosphatase and alanine transaminase activity remained within normal ranges throughout the treatment period, and adverse side effects were not noted (Sharp, 1991). Doses as high as 10–12 mg/kg/day have also been recommended in dogs. Fluconazole is also at least as effective as ketoconazole for the treatment of dogs with *Malassezia* dermatitis (Sickafoose et al., 2010). Fluconazole is associated with survival to clinical remission in 75% of dogs with blastomycosis, which was not statistically different than the 90% survival with itraconazole (Mazepa et al., 2011). The cost of fluconazole therapy in that study was approximately one-third that of itraconazole, and both drugs caused a similar incidence of hepatotoxicosis (elevated alanine aminotransferase, ALT). For cats with systemic cryptococcosis, clinical studies have shown a benefit from a dose of 100 mg/cat/day in one or two divided doses. A practical dose is one 50-mg tablet per cat, once a day, or twice daily for refractory cases. Other reported doses are in the range of 2.5–5 mg/kg once a day (Hill et al., 1995). Pharmacokinetic studies support a dose of 50 mg/cat per day for nasal or dermal cryptococcosis (Vaden et al., 1997).

Exotic animals: The doses for exotic animals are listed in Table 38.4. The half-life can be prolonged in reptiles because of the dependence on renal elimination. Thus, the half-life was 138 hours in turtles when injected SC, which allows for treatment once every 5 days (Mallo et al., 2002).

Large animals: Oral absorption in horses is reported to be greater than 100% (Latimer et al., 2001). From this cited study a dosing regimen of a loading dose of 14 mg/kg orally, followed by 5 mg/kg q 24 h was derived for horses to produce sufficient concentrations in plasma and tissues. This dose has been successful in treating cryptococcal meningitis and optic neuritis (Hart et al., 2008), and nasal conidiobolomycosis lesions in adult horses (Taintor et al., 2004) as well as disseminated candidiasis in foals (Reilly and Palmer, 1994).

Adverse Effects

Fluconazole has been generally well tolerated, with mild adverse effects being reported in 5–30% of cases. The GI tract was most frequently involved, followed by the CNS and skin. Elevations in hepatic enzymes have been observed, in small animals and horses, sometimes necessitating termination of treatment. Hematological abnormalities, including anemia, leukopenia, neutropenia, and thrombocytopenia, have been reported in people. In subacute toxicity studies in dogs, the highest dose tested (30 mg/kg) caused slight increases in liver weight, hepatic fat, and plasma transaminase activity. Although there is no evidence of mutagenicity or carcinogenicity, its use in pregnant patients is not recommended. However, it has been used successfully with no observed adverse effects on the fetus in horses in the seventh and tenth month of gestation (Taintor et al., 2004).

Drug Interactions

Drug–drug interactions are less frequently reported with fluconazole than other azole antifungals; however, they do occur. Fluconazole has been shown to significantly increase cyclosporine concentrations in both normal and renal transplanted dogs (Katayama et al., 2008, 2010a). Treatment with fluconazole has been shown to significantly prolong anesthesia times in horses following induction regimens that include midazolam (Krein et al., 2014). Compared to ketoconazole, there is little evidence of testosterone or other steroid biosynthesis inhibition (Shaw et al., 1987) in human or animal patients (VanCauteren et al., 1987b).

Itraconazole

Itraconazole (Sporanox®) was approved for use in the United States in 1992. Of several triazole compounds screened, itraconazole, first synthesized in 1980, was selected for further clinical development due to several criteria: (i) 5–100 times better in vitro and in vivo potency than ketoconazole, (ii) good activity against *Aspergillus* spp., (iii) activity against meningeal cryptococcosis in animal models, (iv) fewer adverse effects compared to ketoconazole, and (v) favorable pharmacokinetics (Cauwenbergh et al., 1987).

Itraconazole is a weak base (pK_a = 3.7), is highly lipophilic (logP = 5.66), and is practically insoluble in water. There are several different formulations available. The intravenous formulation is rarely used in veterinary medicine due to expense as well as instability once reconstituted. There are three oral formulations available. The oral capsules were the first formulation marketed and they are still commonly used. They are available in 100 mg dose strength, and consist of drug coated onto small sugar spheres. The capsules require an acid environment for dissolution and therefore absorption is often highly variable. There is also an oral solution approved for use in humans that contains 10 mg/ml of itraconazole complexed with hydroxypropyl-β-cyclodextrin, to increase the solubility. This product has been demonstrated to have higher, less variable absorption in humans, cats, and horses (Willems et al., 2001; Boothe et al., 1997; Davis et al., 2005; Mawby et al., 2016) but is bioequivalent to the capsules in dogs

Table 38.4 Selected systemic antifungal drugs used in exotic animal species

Species	Drug	Disease treated	Dosing protocol	Reference
Passerine and Softbill Birds	Fluconazole	Candidiasis	2–5 mg/kg PO q24h for 7–10 days	Dorrestein, 2000
	Griseofulvin	Dermatophytosis	20 mg/kg PO q24h for 4–6 weeks	
	Itraconazole	Aspergillosis	5–10 mg/kg PO q12–24h in orange juice or 0.1N HCl for 14 days	
	Ketoconazole	Dermatophytosis	20–30 mg/kg PO q12h for 14–30 days	
	Miconazole	Candidiasis or cryptococcosis	10–20 mg/kg IM or IV q8–24h	
	Nystatin	Intestinal candidiasis	100,000 IU/l of drinking water or 200,000 IU/kg soft food for 3–6 weeks	
Psittacine Birds	Fluconazole	Candidiasis	2–5 mg/kg PO q24 h for 7–10 days	Tully, 2000
	Flucytosine	Aspergillosis	60–150 mg/kg PO q12h in adults; 100–250 mg/kg PO q12h in neonates. Usually given in combination with amphotericin B	
	Itraconazole	Aspergillosis	5–10 mg/kg q12h for 4–5 weeks; 5 mg/kg q24h in African grays	
	Ketoconazole	Candidiasis	20–30 mg/kg q12h in orange or pineapple juice, lactulose, or methylcellulose for 14–30 days	
	Voriconazole	Aspergillosis	12–18 mg/kg oral q12h	Flammer et al., 2008
	Miconazole	Candidiasis or cryptococcosis	20 mg/kg IV q8h	
	Nystatin	Intestinal candidiasis	100,000–300,000 IU/kg PO q8–12h	
Raptors	Fluconazole	Mycelial candidiasis, systemic mycosis	5–15 mg/kg PO q12h for 14–60 days	Huckabee, 2000
		Gastrointestinal and systemic candidiasis	2–5 mg/kg PO q24h for 7–10 days	
	Flucytosine	Aspergillosis	120 mg/kg PO q6h; 20–30 mg/kg PO q6h for 60–90 days; 50–75 mg/kg PO q8h in combination with amphotericin B	
		Candidiasis	250 mg/kg PO q12h	
	Itraconazole	Aspergillosis	15 mg/kg PO q12h for 4–6 weeks	
	Ketoconazole	Candidiasis	15 mg/kg PO q12h	
		Aspergillosis	30–60 mg/kg PO q12h for 14–30 days	
	Nystatin	Intestinal candidiasis	100,000–300,000 IU/kg PO q8–12h	
Pet Fish	Itraconazole	Systemic mycoses	1–5 mg/kg q24h in feed for 1–7 days	Mashima and Lewbart, 2000
	Ketoconazole	Systemic mycoses	2.5–10 mg/kg PO, IM or ICe	
Ferrets	Amphotericin B	Systemic mycoses	0.4–0.8 mg/kg IV once a week to a total dose of 7–25 mg	Williams, 2000
	Griseofulvin	Dermatophytosis	25 mg/kg PO q24h for 3–4 weeks	
	Ketoconazole	Systemic mycoses	10–30 mg/kg PO q12h–24h	
Hedgehogs	Griseofulvin	Dermatophytosis	25–50 mg/kg PO q24h	Lightfoot, 2000
	Itraconazole	Systemic mycoses	5–10 mg/kg PO q12–24h	
	Ketoconazole	Systemic yeast/fungal infections	10 mg/kg PO q24h	
	Nystatin	Yeast infections	30,000 IU/kg PO q8–24h	
Marsupials	Griseofulvin	Dermatophytosis	20 mg/kg PO q24h for 30–60 days	Johnson-Delaney, 2000
	Nystatin	Candidiasis	5000 IU/kg q8h for 3 days	

(*continued*)

Table 38.4 (*Continued*)

Species	Drug	Disease treated	Dosing protocol	Reference
Rabbits	Amphotericin B	Systemic mycoses	1 mg/kg IV q24h	Ivey and Morrisey, 2000
	Fluconazole	Systemic mycoses	25–43 mg/kg slow IV q12h	
	Griseofulvin	Dermatophytosis	12.5–25 mg/kg PO q12–24h for 10–42 days	
	Ketoconazole	Dermatophytosis	10–40 mg/kg PO q24h for 14 days	
Rodents	Amphotericin B	Candidiasis	0.43 mg/kg PO or 0.11 mg/kg SC in mice	Adamcak and Otten, 2000
	Griseofulvin	Dermatophytosis	25 mg/kg PO q24h for 14–28 days in gerbils, guinea pigs, hamsters, and rats; 14 days in mice; 28–40 days in chinchillas	
	Itraconazole	Systemic mycoses	5 mg/kg PO q24h in guinea pigs; 50–150 mg/kg q24h in mice; 2.5–10 mg/kg PO q24 in rats	
	Ketoconazole	Systemic mycoses/candidiasis	10–40 mg/kg PO q24h for 14 days in all species	
Amphibians	Amphotericin B	Systemic mycoses	1 mg/kg ICe q24h for 14–28 treatments	Walker and Whitaker, 2000
	Fluconazole	Systemic mycoses	60 mg/kg PO q24h for 7 days	
	Itraconazole	Superficial and systemic mycoses	2–10 mg/kg PO q24h for 14–28 days	
	Ketoconazole	Systemic mycoses	10–20 mg/kg PO q24h for 14–28 days	
Chelonians	Amphotericin B	Aspergillosis	1 mg/kg ICe q24h for 2–4 weeks	Bonner, 2000
	Griseofulvin	Dermatophytosis	20–40 mg/kg PO q72h for 5 treatments	
	Itraconazole	*Sceloporus* sp.	20–30 mg/kg PO q6–8h in the spiny lizard	
	Ketoconazole	Systemic mycoses	25 mg/kg PO q24h for 2–4 weeks in turtles; 15 mg/kg PO q24h (27°C) in the gopher tortoise	
	Nystatin	Enteric fungal infections	100,000 IU/kg PO q24h for 10 days in turtles	
Reptiles	Amphotericin B	Systemic mycoses	1 mg/kg IT q24h for 14–28 days	Funk, 2000
	Fluconazole	Systemic mycoses	2–5 mg/kg PO q24h for 5–21 days in lizards and snakes; can also mix 100 mg with 20 ml of nystatin and give PO at 0.5–0.6 ml/kg	
	Fluconazole		For sea turtles, a loading dose of 21 mg/kg, followed by 10 mg/kg every 5 days, injected SC (Mallo et al., 2002)	
	Griseofulvin	Dermatophytosis	20–40 mg/kg PO q72h for 5 treatments in snakes	
	Ketoconazole	Superficial and systemic mycoses	25 mg/kg PO q24h for 3 weeks in snakes	
	Nystatin	Enteric fungal infections	100,000 IU/kg PO q24h	

(Hasbach et al., 2017). In cats, the oral solution was absorbed five times higher than the oral capsule (Mawby, Whittemore, and Papich unpublished data). A third oral formulation is licensed for use in cats in the United States (Itrafungol, Elanco). This formulation is also an oral solution (10 mg/ml itraconazole) with similar solubilizing agents and excipients as the human formulation.

Spectrum of Activity

Itraconazole has been tested both in vitro and in vivo against a wide variety of fungi (for review see Perfect et al., 1986; VanCutsem et al., 1987; VanCutsem, 1990; Cauwenbergh and DeDonker, 1987). It was found to be effective against virtually all medically important fungi, including *Microsporum, Trichophyton,* *Candida, Malassezia, Sporothrix, Pythium, Histoplasma, Aspergillus, Blastomyces, Coccidioides*, and *Cryptococcus*. It has little activity against *Fusarium* sp.

Like other azole antifungal drugs, the AUC/MIC is the best surrogate marker to predict efficacy. However, the most often reported drug concentrations from studies in humans have been the plasma concentrations measured at the lowest point (trough, or C_{min}) during multiple dosing. In these studies (Goodwin and Drew, 2008) the trough concentrations greater than 0.5 to 1.0 μg/ml have been associated with clinical success.

Pharmacokinetics

Absorption is increased by an acid environment and when taken with meals and is less variable than ketoconazole absorption. Bioavailability increases from 40% after fasting to 99.8% when given with a meal (VanCauteren et al., 1987a), except in horses. Due to the low solubility of itraconazole, commercially available formulations include solubility enhancers. Without these specialized formulations, absorption is negligible. Comparison of the oral absorption of Sporanox® capsules, generic and compounded itraconazole capsules showed that, in dogs, the formulations are not bioequivalent (Mawby et al., 2014). Although therapeutic concentrations are reached with the generic formulations, relative bioavailability of the compounded capsules is only approximately 5%. The compounded suspension and capsule had negligible oral absorption in cats (Mawby et al., 2016). This feature of itraconazole also has been demonstrated in other species as well, including birds and horses. Thus, the use of compounded itraconazole formulations is not recommended.

Itraconazole is highly (99.8%) protein bound (95% to albumin and 5% to red blood cells) (Heykants et al., 1987); however, due to its lipophilicity and even higher affinity for tissue proteins, it is extensively distributed throughout the body. Tissue to plasma concentration ratios range from 1 : 1 in brain to 8 : 1 in keratin to 25 : 1 in fat stores. Highest tissue levels are seen in the liver and adrenal cortex (Heykants et al., 1987). High tissue binding also produces a very large volume of distribution (Troke et al., 1990; Heykants et al., 1990) and low plasma concentrations. Although it does not reach high concentrations in the CSF compared to fluconazole, itraconazole was found to be effective in treating meningeal cryptococcosis in both mouse and guinea pig models (Perfect et al., 1986).

Itraconazole is extensively metabolized, with less than 1% of the active drug and approximately 35% of inactive drug (as more than 10 metabolites) excreted in the urine. The major metabolite, hydroxyitraconazole, has similar antifungal activity to the parent drug, and is often found at concentrations two to three times higher than itraconazole in the plasma in humans (Willems et al., 2001). The metabolite to parent drug ratio is reported to be similar in dogs (Yoo et al., 2002); however, this metabolite has not been found in either cats (Itrafungol®, package insert) or horses (Davis et al., 2005). The predominant route of elimination for itraconazole is in the bile. Because of the increased metabolic stability of the triazole ring versus the imidazole ring (Richardson et al., 1990), itraconazole has a longer half-life (17–25 hours) than ketoconazole (8 hours) in humans. There is disagreement about the elimination rate since the terminal half-life in the dog has been reported to be 8–12 hours (VanCauteren et al., 1987a) and 44–58 hours (Heykants et al., 1987). Differences in study methods, assay sensitivity, and pharmacokinetic analysis may account for this discrepancy. More important than plasma half-life, therapeutically active concentrations are maintained much longer in tissues than in plasma. For example, itraconazole can be detected for 4 days in vaginal epithelium and for 4 weeks in skin and nails after cessation of therapy. These long-lasting tissue concentrations account for the ability to administer this drug intermittently for some fungal infections, as will be discussed below in Section Clinical Use. Itraconazole, like ketoconazole, exhibits nonlinear pharmacokinetics; steady-state concentrations were found to be three times higher after 14 days of therapy than those predicted by a single dose, and the half-life was seen to increase from 24 to 36 hours (Heykants et al., 1990).

Pertinent to the pharmacokinetics is the ability of itraconazole to inhibit drug metabolizing enzymes. Itraconazole and its metabolites are cytochrome P450 inhibitors (Templeton et al., 2008). Metabolizing enzymes may be saturated producing nonlinearity in elimination. In addition, repeated dosing may produce a time-dependent decrease in clearance and accumulation (Templeton et al., 2008). Therefore, with repeated dosing, the clearance may decrease and half-life increase. Coadministration of itraconazole and cyclosporine has been shown to result in increased cyclosporine concentrations in cats (Katayama et al., 2010b).

Clinical use

Small animals: Itraconazole is one of the most commonly administered oral antifungal agents for small animals. It has no endocrine effects compared to ketoconazole and is better tolerated. Itraconazole is highly bound in plasma and there is strong binding to keratin producing drug concentrations in skin that persist 2–4 weeks after cessation of drug therapy. It may be excreted into the sebum, increasing the concentrations in skin. This allows for pulse dosing for some diseases. *Histoplasma, Cryptococcus*, and *Blastomyces* are highly susceptible; *Candida, Aspergillus,* and *Penicillium* are less sensitive. Itraconazole also has been used to treat cutaneous leishmaniasis because the *Leishmania* organism has ergosterol in high concentrations in its cell wall.

Cats: Itraconazole is probably better tolerated in cats than ketoconazole. Nevertheless, adverse effects are still possible. Since most adverse effects are dose related, one is advised to lower the dose in animals in which adverse effects are observed. One report indicated that there were dose-related GI effects of anorexia and vomiting in cats from administration of itraconazole (Mancianti et al., 1998).

The dosing regimens for cats were reviewed by Moriello (2004). Doses in cats vary from 5–10 mg/kg once a day, orally for at least 56 days, to 10 mg/kg once a day, for 28 days, followed by pulse therapy of 1 week on/1 week off. Lower doses of 1.5 to 3 mg/kg once daily for cycles of 15 days at a time are also used. The most recent regimen to be studied is 100 mg capsule per cat every other day for up to 8 weeks. This regimen yielded average therapeutic trough plasma concentrations (>0.5 μg/ml) within 3 weeks, however two of the ten cats in the study developed reversible adverse effects (Middleton et al., 2016).

The availability of a commercial form for cats has helped to define the use in this species. As mentioned previously, itraconazole (Itrafungol®) 10 mg/ml oral solution is registered for use in cats to treat dermatophytosis (not registered in the USA). The treatment schedule consists of once-daily doses of 5 mg/kg for three 1-week cycles. After each week of treatment, it should be followed by a week without treatment (week on/week off schedule). This schedule has been evaluated in cats and maintains drug concentrations in hair during the non-treatment phase (Vlaminck and Engelen, 2004).

Itraconazole has been compared to ketoconazole, with each drug administered at doses of 10 mg/kg/day for the treatment of experimentally induced feline disseminated cryptococcosis (Medleau et al., 1990). After 3 months of therapy, the infection had been cleared by both drugs as determined by cryptococcal antigen titers and CSF culture. Three months following therapy all animals remained clinically normal, and titers and CSF cultures remained negative. Although both antifungals brought about resolution of the disease, all cats receiving ketoconazole became anorectic and lost weight, requiring dosage adjustments. This was not seen with itraconazole, and in fact the animals receiving this drug gained weight during the study. Itraconazole has also been used in naturally occurring cryptococcal infections (Medleau, 1990), where an increase in treatment failure was noted in cats that were seropositive for FIV or feline leukemia virus (FeLV).

Dogs: In dogs, the most extensive study has been for treatment of blastomycosis (Legendre et al., 1996). In a study of 112 dogs, 5 mg/kg/day was as effective as 10 mg/kg/day. With a 60-day course of therapy, 54% of dogs were cured. Itraconazole has been used to treat ocular and systemic blastomycosis in dogs. When given 5 mg/kg itraconazole twice a day for 60 days, 76% of eyes with posterior segment disease other than optic neuritis and 18% and 13% of eyes with anterior uveitis or endophthalmitis, respectively, recovered (Brooks et al., 1992). Pulse dosing has also been evaluated in dogs. Itraconazole doses of 5 mg/kg PO q 24 h for 2 consecutive days per week for 3 weeks was found to be as effective as a dose of 5 mg/kg PO q 24 h for 21 consecutive days in the treatment of *Malassezia* dermatitis and otitis (Pinchbeck et al., 2002).

Itraconazole has been successfully used in both the prevention and the treatment of aspergillosis in caged birds. A dose of 20 mg/kg daily for at least 30 days was used to successfully treat five of 12 presumed cases of *Aspergillus* infections in penguins. This same author suggests its prophylactic use in penguin chicks (Shannon, 1992). A different treatment protocol was recommended for aspergillosis in raptors. Birds are treated with 10 mg/kg twice daily in combination with amphotericin B nebulization three times a day for 20 minutes. Treatment for some cases lasted as long as 6 weeks. These authors also recommend the prophylactic use of itraconazole whenever the clinician expects increased risk for the disease (Forbes et al., 1992). Other antifungal dosing regimens in birds and other exotic animal species are listed in Table 38.4.

Large animals: Itraconazole has been reported to be effective in horses for the treatment of mycotic rhinitis, osteomyelitis, and guttural pouch mycosis (Korenek et al., 1994; Foley and Legendre, 1992; Davis and Legendre, 1994). A pharmacokinetic study showed that the oral solution at a dose of 5 mg/kg q 24 h will produce adequate levels in blood and tissues for successful treatment (Davis et al., 2005). However, the use of the oral liquid will require large volumes — most likely requiring intragastric administration in horses — and the drug is very expensive. The oral capsules have a lower bioavailability and higher doses or more frequent dosing intervals are recommended. There are no reports of the use of this drug in food animals, and there are no approved formulations for these species.

Adverse Effects

Itraconazole is up to 125 times more selective for fungal P450 systems than mammalian liver enzymes in certain in vitro preparations (Vanden Bossche, 1987). It also does not inhibit P450 systems in the testis, adrenal, or liver in vivo (Vanden Bossche et al., 1990). In clinical studies, 100 mg of itraconazole given to humans each day for 30 days had no effect on serum testosterone or cortisol levels (DeCoster et al., 1987). Similarly, there were no changes in testosterone and cortisol concentrations in rats and dogs receiving daily itraconazole for at least 1 month.

The biochemical basis for the specificity of itraconazole toward fungal P450 is thought to be dependent upon the hydrophobic nonligand portion of the molecule and its affinity for the apoprotein portion of the cytochrome molecule (Vanden Bossche et al., 1990). The resulting lack of significant inhibition of liver microsomal enzymes results in itraconazole's inability to affect other drugs' metabolism. Although the clinical significance is as yet unknown, drugs that can inhibit or stimulate liver degradative enzymes are able to alter the pharmacokinetics of itraconazole. Even though itraconazole is primarily cleared by hepatic metabolism, there appears to be no need for dosage adjustments in patients with liver disease (Heykants et al., 1987). As with ketoconazole, itraconazole's oral absorption is pH dependent; therefore, dosage adjustments may be necessary when gastric pH is increased.

Because itraconazole is better tolerated than ketoconazole, it is used as the drug of choice for long-term treatment. Dogs, cats, and exotic and zoo animals have received this drug for weeks without adverse effects. The capsules have been administered for up to 6 months in horses with no reported adverse effects. Nevertheless, adverse effects are still possible. Since most adverse effects are dose related, one is advised to lower the dose in animals in which adverse effects are observed. According to Legendre (1995) about 10% of dogs receiving recommended doses develop hepatic toxicosis. Liver enzyme elevations may occur in 10–15% of dogs. Itraconazole has been well tolerated by clinically ill cats, although one case of fatal drug-induced hepatitis has been reported (Medleau, 1990). Anorexia may occur as a complication of treatment, especially with high doses and high serum concentrations. It usually develops in the second month of therapy in dogs. In cats there seem to be dose-related GI effects of anorexia and vomiting (Mancianti et al., 1998). Drug-related cutaneous vasculitis has also been reported as a complication of itraconazole therapy in dogs (Nichols et al., 2001).

Dogs chronically administered itraconazole (2.5, 10, or 40 mg/kg daily for 3 months) had no significant alterations in mortality rate, behavior, appearance, food consumption, body weight, hematological values, serum and urine chemistry, or gross pathology (VanCauteren et al., 1987b). Subacute toxicity studies in rats revealed increased adrenal gland weight and the accumulation of proteinaceous material in the mononuclear phagocyte system at doses of 40 and 160 mg/kg. Since the mononuclear phagocyte system is responsible for clearing the host of a fungal infection, the clinical importance of this toxic effect is undetermined. Although not teratogenic at 10 mg/kg, maternal toxicity, embryo toxicity, and teratogenicity were observed at 40 and 160 mg/kg in rats (VanCauteren et al., 1987b); therefore, its use in pregnant animals is not recommended.

Postmarketing drug monitoring in humans has shown that itraconazole may cause or exacerbate underlying heart conditions. There is a dose-related negative inotropic effect seen in both healthy human volunteers and in anesthetized dogs. Owners should therefore be counseled to monitor the patients for signs of heart failure and to discontinue the drug if clinical signs are observed.

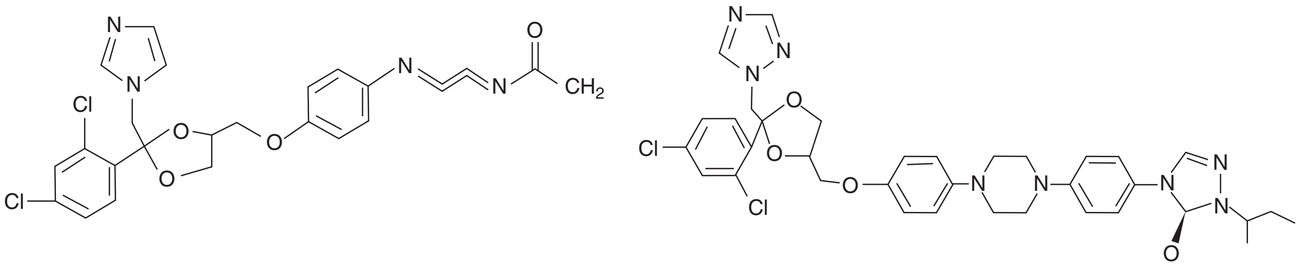
Mild to moderate kidney disease has not been reported to change the pharmacokinetic clearance of itraconazole in humans. However, if the intravenous formulation or the oral Sporanox® solution is used, renal failure may decrease the elimination of the carrier molecule hydroxypropyl-β-cyclodextrin. Therefore, the oral capsules are recommended for use in these patients.

Voriconazole

The newest triazole to be investigated in animals is voriconazole (Vfend®). Voriconazole is similar in structure to fluconazole (Figure 38.4); however, the substitution of a fluoropyrimidine ring for one of the triazole moieties and the additional of a methyl group to the propanol backbone increases the spectrum of activity and potency as well as the fungicidal activity against some species of molds, including *Aspergillus* and *Fusarium* spp. In a survey of fungal pathogens, voriconazole inhibited greater than 95% of *Aspergillus* with a concentration less than or equal to 1 μg/ml (Diekma et al., 2003). It is more lipophilic than fluconazole, more water soluble than itraconazole or ketoconazole, with intermediate protein binding. These properties allow for excellent oral bioavailability and tissue distribution. In people, the plasma concentrations were highly variable among individuals, which is caused by variations in hepatic metabolism, other medications coadministered, and nonlinear elimination. The pharmacodynamic parameters associated with clinical cure are an AUC/MIC plasma concentration of 20–25, or a plasma concentration above 2 μg/ml.

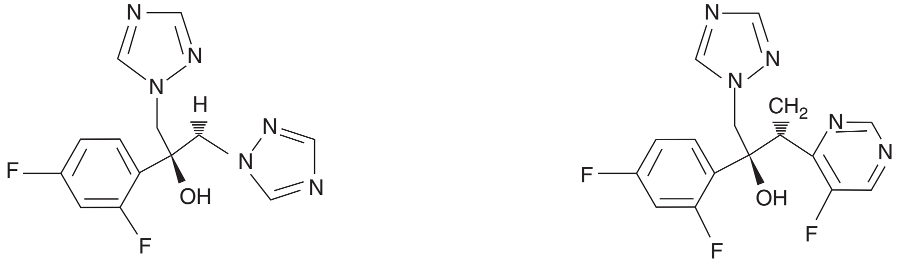
Pharmacokinetics

The pharmacokinetics of voriconazole have been investigated in dogs, horses and avian species, with preliminary data available for llamas and cats. Across species, the pharmacokinetics vary widely. Experimental studies in dogs have shown rapid and complete absorption of the drug following oral administration (Roffey et al., 2003). Half-life is short (approximately 3 hours), and at a dose of 6 mg/kg/day orally, plasma concentrations remained above the target MIC of 1 μg/ml for only 15 hours and the target AUC : MIC ratio of 20–25 for free drug concentrations were not reached (Lemetayer et al., 2015).



Ketoconazole

Itraconazole



Fluconazole

Voriconazole

Figure 38.4 Chemical structures of commonly used systemic azole antifungal drugs.

Although the authors of that study state twice-daily dosing may be necessary, an effective dose cannot be extrapolated from current data as voriconazole exhibits nonlinear pharmacokinetics in this species, with a ninefold increase in plasma concentrations seen following a fourfold increase in dose (Lemetayer et al., 2015; Roffey et al., 2003). Interestingly, autoinduction of drug metabolism has been shown to occur in dogs, further complicating dosing recommendations as an increase in dose may be required with multiple administrations. Although drug was detected in body fluids, including CSF, aqueous humor and synovial fluid, it was found at a lower percentage than other reported species (Lemetayer et al., 2015).

Whereas the metabolism appears to increase with repeated doses in dogs causing lower concentrations after multiple doses, the opposite phenomenon occurs in cats. In the studies by Vishkautsan et al. (2016), the half-life was much longer in cats than dogs. The IV half-life was 12.4 hours, but after oral administration of 4–6 mg/kg, the half-life was 43 hours (± 9.02) producing an inflated oral absorption of 264%. Moreover, in the multiple dosing study of 25 mg per cat loading dose followed by 12.5 mg per cat every 48 hours, accumulation was observed steadily to 14 days and steady state was not achieved.

The pharmacokinetics of voriconazole have been studied following single and multiple dose administration in the horse (Davis et al., 2006; Colitz et al., 2007). In these cited equine studies, voriconazole had excellent oral absorption (95% and 100%) and a moderate half-life (8–13 hours) following oral administration. The oral dose used in the study by Davis et al. (2005) was 4 mg/kg and produced plasma concentrations higher than necessary for the treatment of most common veterinary pathogens, with the exception of *Fusarium* sp. The study by Colitz et al. (2007) used 3 mg/kg orally twice daily and produced concentrations above the minimum level necessary for successful treatment. When administered at 4 mg/kg orally once a day for 2 weeks in nonfasted horses, there was no statistically significant difference between voriconazole concentrations in plasma and body fluids when comparing days 7 and 14, suggesting enzyme induction may not be prominent in this species (Passler et al., 2010). In horses, voriconazole has good distribution into the aqueous humor, CSF, peritoneal fluid, pulmonary epithelial lining fluid, synovial fluid, urine, and periocular tear film. The concentrations in plasma, tissues, and other fluids exceed the minimum concentration recommended for successful therapy (Goodwin and Drew, 2008).

After oral administration of single doses ranging from 6 to 18 mg/kg in African grey parrots, a follow-up study examined multiple doses at the highest dose (18 mg/kg every 12 hours for 9 days). Compared to mammals, the elimination half-life was short at 1.1 to 1.6 hours (Flammer et al., 2008). A similar study looked at 18 mg/kg q 8 h for 11 days in Hispaniolan Amazon parrots, with similar results (Sanchez-Migallon Guzman et al., 2010). With multiple doses the kinetics changed, suggesting induction of the hepatic metabolism as mentioned for dogs above, and requiring dose adjustment for long-term treatment. Polyuria was observed in the treated birds, but no other adverse reactions were reported.

A single dose pharmacokinetic study is published on voriconazole in alpacas (Chan et al., 2009). Oral absorption is low in this species, and high daily doses would likely be needed for treatment success.

Clinical Use

Clinical experience with this drug is currently limited due to potential adverse effects, as well as cost. Successful reports of treatment of miscellaneous fungal infections are available, including intracranial phaeohyphomycotic granuloma and *Exophilia dermatitidis* in dogs, and pulmonary aspergillosis in a foal (Bentley et al., 2011; Murphy et al., 2011; Hilton et al., 2009). In these species, the most common clinical use of voriconazole is as a topical or local ocular therapy. Topical administration of the commercially available intravenous voriconazole solutions diluted to 1%, has good ocular penetration through an intact cornea with little to no local irritation (Clode et al., 2006). Intracorneal administration of 5% voriconazole solution has also been reported to result in resolution of clinical disease, specifically stromal fungal abscessation and secondary uveitis (Smith et al., 2014). At this time, the use of voriconazole in cats cannot be recommended.

Birds: The experience with voriconazole in birds has been reported by Flammer et al. (2008). On the basis of this study, the authors concluded that 12–18 mg/kg orally twice daily would be sufficient for treatment of some *Aspergillus* infections; higher doses may be needed for some infections and to maintain concentrations during long-term treatment.

Adverse Effects

Voriconazole appears to be safe for use in horses following multiple doses. The only adverse event reported in this species was in a single horse that developed pruritis after drug administration; however, these signs were controlled with administration of an antihistamine 2 hours prior to dosing (Passler et al., 2010). Except for the polyuria observed in birds, the drug also appears to be safe in the avian species studied. In dog studies using multiple doses, several dogs showed mild to moderate gastrointestinal disturbances (loss of appetite and diarrhea) and one dog had mild increases in liver enzymes (Lemetayer et al., 2015). Intravenous injection of 10 mg/kg in dogs results in severe, acute toxicity.

Cats appear to be the most susceptible to adverse drug events caused by voriconazole administration. Adverse effects in cats involving the gastrointestinal tract, eyes, and neurological function have been reported (Quimby et al., 2010; Smith and Hoffman, 2010; Vishkautsan et al., 2016). Inappetance, lethargy, and weight loss are common. Ataxia and hindlimb paresis that resolved following withdrawal of drug administration were noted in several cats. One proposed mechanism for the neurotoxicity associated with azole antifungals is through inhibition of voltage-gated calcium channels in neuronal cells (Heusinkveld et al., 2013). Visual abnormalities noted include mydriasis, decreased to absent pupillary light responses, and decreased menace response. On the other hand, in the study by Vishkautsan et al. (2016), miosis occurred from an unknown mechanism. Also noted in that study was excess salivation from administration of the oral suspension, but not from the oral tablet. Azotemia has also been noted, although it may be attributable to dehydration secondary to GI disturbances, or concurrent NSAIDs administration, rather than voriconazole having a direct nephrotoxic effect. One cat was also described to have a cutaneous drug reaction. In the case reports involving cats, they were administered doses that were similar to the canine dose, or a dose extrapolated from people (i.e., up to 13 mg/kg per day). As the study by Vishkautsan et al. (2016) showed, these doses are probably too high because of the slow clearance of voriconazole in cats compared to other animals. Prolonged QT intervals and arrhythmias have been reported in both dogs and cats. Because of adverse effects in people, it is recommended that in humans doses be adjusted to produce trough concentrations no higher than 4–6 μg/ml in order to avoid toxicity (Ashbee et al., 2014).

Posaconazole

Posaconazole (Noxafil®) is one of the newest azole antifungal drugs introduced. It is approved for use in people but its use in animals has been limited to just a few case reports and pharmacokinetic studies. Posaconazole resembles itraconazole in structure. It is used for invasive fungal infections, including those caused by *Aspergillus* and *Candida*. It is also active against dermatophytes, *Histoplasma capsulatum, Blastomyces dermatitidis, Coccidioides immitis*, and *Cryptococcus neoformans*. Its advantage over other azole drugs is the activity against *Fusarium* and *Mucorales* (formerly called Zygomycetes), such as *Mucor* and *Rhizopus*. It has some chemical properties that are similar to itraconazole and is a substrate for CYP450 enzymes and P-glycoprotein. As with other azoles, the pharmacokinetic/pharmacodynamic parameter that best correlates with clinical success is the plasma concentration AUC/MIC. For treating *Aspergillus* this ratio was above 200; for treating *Candida* the ratio was only 15. If AUC/MIC ratios cannot be monitored, it is suggested to maintain plasma concentrations above (C_{max}) 1.48 μg/ml or an average concentration at least 1.25 μg/ml (Goodwin and Drew, 2008). Additional information has indicated that prophylactic efficacy for invasive fungal infections is optimal when plasma concentrations of posaconazole exceed 0.7 μg/ml 3–5 hours after dosing in a multiple-dose regimen. It is available as an oral suspension containing 40 mg/ml posaconazole

Table 38.5 Topical antifungal products for dogs and cats

Antifungal agent	Product	Indication	Other ingredients
Clotrimazole	Otomax	*Malassezia pachydermatis*	Betamethasone, Gentamicin
Ketoconazole	Keto-Tris Flus	*Malassezia pachydermatis*	Tromethamine (Tris) EDTA
Miconazole	Surolan, and generic	*Otitis externa*	Polymyxin
Nystatin	Dermalone	*Malassezia pachydermatis* (weak activity)	Neomycin
Posaconazole	Posatex	*Malassezia pachydermatis* (with activity against other fungi)	Mometasone, orbifloxacin
Thiabendazole	Tresaderm	*Malassezia pachydermatis*	Dexamethasone, Gentamicin

(Noxafil) and 100 mg delayed-release tablets (Noxafil). The dose in people is 400 mg twice a day with a meal. If not given with a meal, dosage of 200 mg four times a day is recommended. Posaconazole is also one of the ingredients in an approved ear medication for dogs (Table 38.5). This product (Posatex®), contains orbifloxacin, mometasone (glucocorticoid), and 0.1% posaconazole in an otic suspension for the treatment of otitis externa in dogs associated with *Malassezia pachydermatis* and bacteria.

No dose ranges have been established for animals, but in two case reports on its use in cats with successful treatment, a dose of 5 mg/kg orally, every 24 hours was used without ill effects (Wray et al., 2008). Although it is eliminated via UDP-glucuronidation – which may be deficient in cats – the pharmacokinietics of posaconazole in cats resemble dogs, with oral absorption and half-life that are similar to dogs (Mawby et al., 2016b). Based on preliminary pharmacokinetics, the recommended dose for the oral administration of the suspension in cats is 12–15 mg/kg once daily. In dogs, the oral absorption of the suspension is approximately 26% and the half-life is 24 hours. In dogs, there is a food effect on absorption with oral systemic availability of 11% and 27% in fasted and fed dogs, respectively. The delayed-release tablets also offer a good treatment option for dogs. Bioavailability is increased and the half-life is prolonged (42 hours) (Kendall and Papich, 2015). The suggested dosing regimen for the delayed release tablets is 5 mg/kg orally every other day. It is highly protein bound with binding greater than 97% in dogs. In toxicity studies, dogs have tolerated 30 mg/kg/day for 1 year without any clinical signs. However, histologically, some neuronal vacuolation was observed at this dose. It should not be used during pregnancy because of inhibition of steroidogenesis.

Other Antifungal Agents

Terbinafine

Terbinafine (Lamisil®) is a highly fungicidal agent. It is a synthetic drug of the allylamine class. A closely related drug of the same class is naftifine (Naftin®), which is used as a topical cream for dermatophyte infections in people. Terbinafine inhibits squalene epoxidase to decrease synthesis of ergosterol. Fungal cell death results from disruption of the cell membrane (Balfour and Faulds, 1992).

Spectrum of activity: Terbinafine is active against yeasts and a wide range of dermatophytes. It is fungicidal against *Trichophyton* spp., *Microsporum* spp., and some *Aspergillus* spp. (often excluding *A. fumigatus*). It is also active against *Blastomyces dermatitidis, Cryptococcus neoformans, Sporothrix schenckii, Histoplasma capsulatum, Candida*, and *Malassezia* yeast. In people, it was more effective than griseofulvin for treating dermatophytes, with fewer relapses. There may also be some activity against protozoa (e.g., *Toxoplasma*).

Pharmacokinetics: Oral bioavailability in most species is moderate to high, ranging from 31% in cats (Wang et al., 2012) to >46% in the dog to >85% in mice (Jensen, 1989). Absolute bioavailability in horses is unknown; however, the relative bioavailability of terbinafine in horses was only 16% compared to Greyhounds (Williams et al., 2011). Reported half-lives after oral administration of 20–30 mg/kg to cats, dogs, and horses are approximately 8 hours. Maximum concentrations in cats and dogs (3–4 μg/ml) are much higher than those achieved in horses (0.31 μg/ml) (Wang et al., 2012; Williams et al., 2011). Oral absorption of terbinafine has also been studied in Hispaniolan Amazon parrots, with a dose of 60 mg/kg via intragastric gavage resulting in peak plasma concentrations of 0.11–0.67 μg/ml (Evans et al., 2013). In penguins, a dose of 15 mg/kg terbinafine q 24 h is suggested as a potential treatment option for aspergillosis (Bechert et al., 2010).

The lipophilic nature of terbinafine results in high concentrations in tissues such as stratum corneum, hair follicles, sebum-rich skin, and nails. In people, after 12 days of therapy, the concentrations in stratum corneum exceed those in plasma by a factor of 75. Concentrations in skin may be detected in people as early as 24 hours after oral administration, but maximum concentrations are reached at 7 days. Fungicidal concentrations in nails may require 3 weeks of treatment. Concentrations of terbinafine in the hair of cats being treated for dermatophytosis reach approximately 3.62 μg/g after 120 days of treatment with a dose of 30–40 mg/kg. Like itraconazole, terbinafine is highly protein bound, with values reaching >99% in dogs and rabbits (Jensen, 1989).

Clinical use: Terbinafine has some efficacy for the treatment of dermatophytosis in dogs and cats, as well as *Malassezia* dermatitis in dogs. However, there has been conflicting clinical results. For dermatophytes the most common doses are 30–35 mg/kg once daily in dogs; and for cats, approximately 30 mg/kg per day, or one-quarter tablet for small cats (62.5 mg), half tablet for medium size cats (125 mg), and one tablet for large cats (250 mg), all administered once daily. It should be administered for at least 14 days, but may be extended to 60 days. (Moriello, 2004). Results suggest that it is effective for the treatment of *Malassezia* dermatitis in dogs when given at 30 mg/kg PO, or 30 mg/kg two times per week for at least 3 weeks (Berger et al., 2012). However, the results also showed that this treatment produced insufficient resolution and only partial remission even though there was clinical improvement in both groups. In other studies, terbinafine was as effective as itraconazole in treating shelter cats with *Microsporum canis* dermatophytosis when administered in doses of approximately 20–40 mg/kg/day (Moriello et al., 2013). For treatment of *Malassezia* dermatitis, terbinafine (30 mg/kg) was as effective as ketoconazole in reducing yeast counts on the skin (Rosales et al., 2005). Pharmacokinetic studies of 30–35 mg/kg per day in dogs (Williams et al., 2011; Sakai et al., 2011) showed that sufficient concentrations can be maintained for most of the dose interval for susceptible fungi, but clinical studies are needed to confirm efficacy. By comparison, doses in people are much lower at 125 mg twice daily (approximately 1.8 mg/kg q 12 h), with pediatric doses in the range of 4–8 mg/kg, once a day (Jones, 1995).

When combined with surgical excision, terbinafine has been reported to be successful as an adjunct treatment for intestinal pythiosis and *Cryptococcus neoformans* in dogs (Schmiedt et al., 2012; Olsen et al., 2012). It has been safely used in combination with other drugs, including itraconazole and mefenoxam (Hummel et al., 2011) and a synergistic effect against *Pythium* sp. has been shown when combined with itraconazole (Argenta et al., 2008). In both experimental and clinical trials, the average treatment length lasted approximately 60 days. Most treatments in cats are for at least 14 days, but may extend to 60 days. There are currently no published reports of the use of terbinafine in horses, although it has been used clinically at doses of 20–30 mg/kg orally once daily with some success against nasal and guttural pouch fungal masses.

Terbinafine is available as a 1% topical cream (Lamisil®, available over the counter) and 125 and 250 mg tablets. It has also been compounded as a 0.2% solution for ophthalmic use; however, administration did not result in detectable AH or plasma levels following administration to normal equine eyes, suggesting its use may be limited to superficial infections (Clode et al., 2011).

Adverse effects: In dogs treated with 30 mg/kg, serum ALT concentrations were mildly to moderately elevated in 4 of 10 dogs and ALP was increased in 2 of 10 dogs. Owner reported adverse effects include gastrointestinal disturbances and excessive panting (Berger et al., 2012). Gastrointestinal problems, including vomiting, can be common in cats, and facial dermatitis and pruritus has also been reported. This reaction is a problem because it may be confused with an ongoing dermatophyte infection. Pawing at the ground, curling lips, head shaking, anxiety, and circling was noted in one horse after oral administration, but these signs resolved spontaneously within 30 minutes of onset (Williams et al., 2011). In people, there is a rare incidence of severe hepatic failure and death. Terbinafine does not bind to P450 enzymes as do other antifungal drugs; therefore, it does not cause drug interactions or inhibition of steroid synthesis in animals. No teratogenic effects of the drug have been noted in people.

Lufenuron

Lufenuron (Program®), is an orally active inhibitor of chitin synthesis that is commonly used in dogs and cats for control of flea infestations (see Chapter 43 of this book for ectoparasite treatment). It has been evaluated as an antifungal agent, since fungi also have chitin in their outer cell wall. Although there are reports of successful treatment of dermatophytosis in dogs and cats, the success of this treatment has been controversial. If used for dermatophyte treatment, antifungal doses of lufenuron are higher than those recommended for flea control and have ranged from 50 mg/kg to greater than 250 mg/kg. The dose recommended by one group of investigators is 80–100 mg/kg orally, once every 2 weeks until mycological cure (Ben-Ziony and Arzi, 2000). However, endorsement of this use has diminished and dermatologists have disputed the efficacy because of a high incidence of recurrence. It does not have any in vitro effect on *Aspergillus fumigatus* or *Coccidioides immitis*.

It was hypothesized that lufenuron may have a positive effect against dermatological disease not caused by fungi, and an immunomodulatory effect (Zur and Elad, 2006). This is borne out in a study by Mancianti et al. (2009) in which pretreatment with lufenuron followed by treatment with either griseofulvin or topical enilconazole resulted in clinical and mycological cures at a higher rate than expected with any treatment alone.

Topical or local use of lufenuron may be more efficacious. It has been successfully used as a uterine lavage to treat fungal endometritis caused by *Candida* or

Aspergillus spp. in horses (Hess et al., 2002). However, this too is controversial because lufenuron had no in vitro antifungal activity against *Aspergillus* and *Fusarium* sp., pathogens important to horses (Scotty et al., 2005). If administered orally, absorption in horses is poor and an oral dose cannot be recommended. Lufenuron may also be used in water baths for the treatment of aquatic species and amphibians (Wolfe et al., 2001).

Flucytosine

Flucytosine (5-fluorocytosine, 5-FC, Ancobon) is a synthetic antifungal agent available as an oral preparation. Flucytosine must be taken into the fungal cell by cytosine permeate and then converted to the active form, 5-fluorouracil (5-FU), by a fungal cytosine deaminase enzyme. The 5-FU either is incorporated into RNA, disrupting protein synthesis, or is converted to a related compound that inhibits DNA synthesis. Mammalian cells do not have cytosine deaminase, which results in a selective toxicity of this compound; however, conversion to 5-FU may occur by microbes in the gastrointestinal (GI) tract resulting in 5-FU being taken up by mammalian cells, leading to anemia, leukopenia, and thrombocytopenia (Bennett, 1990).

Fungal mutations leading to alterations in the permease or deaminase enzyme activity has led to the development of resistance to flucytosine, both in vitro and during therapy. To decrease emergence of resistance, the use of flucytosine is limited to adjunct therapy with amphotericin B in systemic infections caused by *Candida* or *Cryptococcus neoformans*. Synergy between these two medications, with as much as a fourfold reduction in the MIC, has been demonstrated, and combination therapy has been successful, particularly in the treatment of cryptococcal meningitis (Medoff et al., 1971; Utz et al., 1975; Bennett et al., 1979). One explanation of this synergism involves the membrane-permeabilizing effects of amphotericin B facilitating flucytosine's entrance into the cell cytoplasm (Medoff et al., 1972). This combination of antifungal drugs is more effective than amphotericin B alone in the treatment of cryptococcal meningitis (Bennet et al., 1979; Utz et al., 1975). Advantages of this combination include a reduction in the amphotericin B dose, thereby limiting nephrotoxicity, as well as prevention of mutants to flucytosine (Drouhet and Dupont, 1987). The combination has been administered to treat cryptococcosis in cats at a dose of 250 mg per cat every 8 hours (25–50 mg/kg every 6–8 hours also has been used). This combination has also been suggested for therapy of acute hematogenously disseminated candidiasis (Horn et al., 1985). Although flucytosine is synergistic with amphotericin B, there is no evidence of synergism for azole antifungal drugs and this combination should not be used.

Adverse effects: In one report, the combination of flucytosine and ketoconazole was administered to two cats and liver injury occurred in one cat (Pukay and Dion, 1984). Myelosuppression is also a concern in cats. Cutaneous and mucocutaneous eruptions have been observed with use of flucytosine in dogs and it is not recommended to be used in dogs for this reason.

Sodium or Potassium Iodide

Iodide compounds were one of the first antifungal drugs used and they are still used today in veterinary medicine. They are inexpensive and can be administered orally, which makes them useful for long-term treatment. The mechanism of action of iodide compounds against fungal organisms is largely unknown, but it may involve stimulating the host's immune response or increasing the elimination of the fungi through the skin or hair. Iodide compounds have been used to treat sporotrichosis in dogs, cats, and donkeys, as well as nasal fungal granulomas caused by *Basidiobolus*, *Conidiobolus*, and *Pseudallescheria* spp. in horses (Koehne et al., 1971; Gonzalez Cabo et al., 1989; Irizarry-Rovira et al., 2000; Owens et al., 1985; Zamos et al., 1996; Davis et al., 2000). Ethylenediamine dihydroiodide (EDDI) is used as a nutritional source of iodine in cattle but also has been used to treat fungal granulomatous disease and infections associated with zygomycetes. The antifungal treatment has been questioned because the efficacy is not established.

The iodide compounds are seldom used as a sole therapy, but rather are used as an adjunct to surgical excision, intralesional injection of other antifungals, or systemic antifungal therapy. Toxic effects are possible (iodism) and may occur secondary to excessive iodide levels. Clinical signs attributable to excess iodine include lacrimation, salivation, coughing, anorexia, dry scaly skin, and tachycardia. Abortion and infertility may also be observed; therefore care should be taken when administering this drug to breeding animals. The recommended doses of 20% sodium iodide solution for dogs is 44 mg/kg PO q 24 h, for cats is 22 mg/kg PO q 24 h, and for horses is 125 ml IV q 24 h for 3 days followed by 30 grams PO q 24 h. Treatment is recommended to extend 30 days beyond the resolution of clinical signs. Iodoject IV is labeled for use in cattle for the treatment of actinomycosis and actinobacillosis at 66 mg/kg IV once a week. The use of this product for fungal infections is considered off label.

Topical Antifungal Agents

Enilconazole

Enilconazole (Imaverol®) is also called *imazalil* in some countries. It is an azole antifungal that has excellent activity against dermatophytes and filamentous fungi and it has a residual effect after application. It has been used in some countries for the topical treatment of dermatophyte infections in dogs and horses. For this treatment, a 10% solution is diluted 50 : 1 to form an emulsion. It may be sponged on the animal every 3 or 4 days for four treatments. It may be applied to the premises as well to prevent recurring infections. In an evaluation of topical therapies for treatment of dermatophyte infections in dogs and cats (White-Weithers and Medleau, 1995), enilconazole was more effective than chlorhexidine, povidone iodine, ketoconazole, sodium hypochlorite, and Captan. The safety of enilconazole has been demonstrated in dogs, even at high doses. One study also showed that enilconazole is safe for treatment of dermatophytes in Persian cats (deJaham, 1998). Enilconazole also has been used to treat nasal aspergillosis in dogs. It has a unique vapor effect and, if instilled into the nasal cavity of dogs, will control fungal growth (Sharp et al., 1991; Sharp and Sullivan, 1992). A dose of 10 mg/kg in a volume of 5–10 ml is infused twice a day for 7–14 days. In one study using this protocol (Sharp et al., 1993) 26 of 29 affected dogs became asymptomatic. A similar protocol has been used for the successful medical treatment of guttural pouch mycosis caused by *Aspergillus* spp. in the horse (Davis and Legendre, 1994).

In the United States, enilconazole is available as Clinafarm®-SG or Clinafarm®-EC. Both are approved for use in poultry hatcheries to control *Aspergillus* organisms on facilities and equipment. Clinafarm®-SG comes in a canister used for smoke generation. Clinafarm-EC is available in a 750 ml bottle containing 13.8% (138 mg/ml) enilconazole. The other ingredients listed on the Material Safety Data Sheet are benzyl alcohol and dioctyl sodium sulfosuccinate. It also contains ethoxylated castor oil. The Canadian formulation of Imaverol® contains polysorbate 20 and sorbitan monolaurate as its inert ingredients with 10% enilconazole as the active drug. The Clinafarm-EC formulation is registered for controlling *Aspergillus* organisms in poultry facilities and equipment by making a 1 : 100 dilution and spraying or fogging the area to be treated. Although there are no published toxicology studies on this particular solution in animals, it has been used in a 50 : 1 dilution applied topically to dogs and cats without adverse effects. One study applied 100 ml of a 2 mg/ml formulation of Clinafarm-EC to cats and was judged to be safe (Hnilica et al., 2000). However, monitoring of liver enzymes was recommended by these authors.

Clotrimazole

Clotrimazole (Lotrimin®) is an imidazole antifungal. It is limited to topical use because after oral administration, the metabolism produces undetectable concentrations of the drug in plasma following repeated dosing. In veterinary medicine, it has been used for treatment of nasal aspergillosis in dogs following infusion of a 1% solution over 1 hour through a nasal catheter (Matthews et al., 1998). It has also been infused into the bladder of dogs and cats with fungal candiduria (Toll et al., 2003; Forward et al., 2002). Clotrimazole can be found in combination with gentamicin sulfate and betamethasone valerate as the product Otomax® and other generic forms that are labeled for the treatment of otitis externa caused by *Malassezia pachydermatitis* or susceptible bacteria in dogs (see Table 38.5).

Miconazole

Miconazole (Conofite® cream) is an imidazole antifungal effective against some fungi refractory to amphotericin B. Rapid clearance and poor oral absorption necessitated frequent IV infusions during hospitalization. In addition, the solubilizing agent in the parenteral form induces histamine-related toxic side effects, making its use hazardous. The intravenous formulation is no longer marketed in the United States. Miconazole has a broad spectrum of activity against yeasts and filamentous fungi, although recent evidence suggest that resistance in yeast isolates has been increasing over the last several years (Beltaire et al., 2012). In veterinary medicine, miconazole is used as a 2% cream or 1% spray or lotion for the treatment of dermatophytosis in dogs and cats. It is also commonly compounded as a 1% solution for topical treatment of keratomycosis. The commercially available cream and lotion formulations should not be used in the eye, as they can cause significant irritation. Miconazole can also be found combined with chlorhexidine as a shampoo for the adjunct treatment of dermatophytosis in animals. Antibacterial activity for miconazole has also been demonstrated, and it is a potential treatment for superficial pyoderma caused by methicillin resistant *S. aureus* (Clark et al., 2015), and otitis externa caused by *E. coli* and *P. aeruginosa* (Pietschmann et al., 2013). Synergism in these cases can be achieved by combining miconazole with chlorhexidine for MRSA and polymyxin B for otitis externa. Other products containing antifungal medications are listed in Table 38.5.

Mefenoxam

Mefenoxam (Subdue MAXX®) is an agricultural fungicide that works by blocking ribonucleic acid (RNA) synthesis via inhibition of ribosomal RNA polymerases. It is used to control plant-pathogenic oomycetes. In vitro, mefenoxam has an MIC_{90} of 1 μg/ml against *Pythium insidiosum* isolates (Brown et al., 2008). Results of acute and chronic dosing studies in dogs performed for the EPA certification revealed a no-effect level (NOEL) of 8 mg/kg/day when dosed for 6 months. Although pharmacokinetic data for dogs are not available, rodent studies showed that mefenoxam administered orally to rats at 2 mg/kg produced maximum blood concentrations of 0.48 μg/ml in males and 0.93 μg/ml in females. Extrapolation of these data has led to dosing dogs at 8 mg/kg/day divided into two treatments orally for the therapy of intestinal pythiosis, with some treatment success when combined with itraconazole and terbinafine (Hummel et al., 2011). The drug has been well tolerated in dogs and no persistent clinical, hematological, or biochemical abnormalities have been detected during up to 18 months of administration. It has also been used both systemically and topically in combination therapy for the treatment of canine cutaneous pythiosis and lagenidiosis, as well as topically for the treatment of equine pythiosis.

Natamycin

Natamycin (Natacyn®) is a polyene antifungal with a mechanism of action similar to amphotericin B. It is approved for use in humans as a 5% ophthalmic suspension. Natamycin has excellent activity against yeasts and filamentous fungi, and it is considered the treatment of choice for *Fusarium* keratomycosis in the horse. It is most commonly used in veterinary medicine for treatment of keratomycosis in horses, although it has also been reported as a topical therapy for nasal aspergillosis as well as guttural pouch mycosis and dermatophytosis in this species (Brooks et al., 1998; Greet, 1981, 1987; Oldenkamp, 1979). Its systemic use is prohibited by expense, as well as toxicity.

Nystatin

Nystatin (Mycostatin®) is also a polyene antifungal that is limited to topical use due to systemic toxicity. Nystatin is not absorbed well from the gastrointestinal tract; therefore, it can be given orally as a "topical" treatment for oral and intestinal candidiasis, particularly in exotic animal species (see Table 38.4). In veterinary medicine, it is most commonly used in combination with antibiotics (neomycin, thiostrepton) and antiinflammatory (triamcinolone) drugs in ointments such as Panalog® and other generic formulations as well as otic preparations (Table 38.5).

Antiviral Therapy

Compared to other classes of antimicrobial drugs, the use of antiviral drugs in veterinary medicine has been limited, with all specific antiviral agents used in an extralabel manner. In human medicine, the use of these drugs is much more prominent due to the success of multiple agent protocols to control human immunodeficiency virus (HIV) and associated AIDS, as well as successful single agent therapies for the treatment of herpesvirus infections, influenza, hepatitis C, and other diseases. In veterinary medicine, the most successful use of antiviral agents has primarily been associated with the treatment of herpesvirus infections, with more limited success against retroviruses. Several antiviral drugs are administered systemically, whereas others are only used topically for the treatment of ocular lesions. Consequently, compared to our human medicine counterparts, the consideration of these agents in this book is limited. Readers are encouraged to consult a human pharmacology textbook for more in-depth discussion of mechanism of action and antiviral spectrum of these agents.

There are key differences between the principles of antiviral therapy as compared to antibacterial therapy. Because viruses use host cellular machinery for replication, it is difficult to achieve selective action against viral replication. In this way, many of the most successful of the antiviral drugs act more similarly to the cytotoxic anticancer drugs, by targeting DNA replication. As a consequence the therapeutic indices of antiviral and anticancer drugs may be similarly narrow. For the nucleoside analogs, which are primarily used in the therapy of DNA viruses, there tends to be an inverse relationship between selectivity for viral replication and toxicity to host cells. Another difference between antiviral and antibacterial drugs is that in vitro testing of the antiviral drugs must utilize a cell culture system to allow viral replication. The concentration of drug that inhibits viral growth by 50% is termed the IC_{50}, but this parameter depends upon numerous factors, and is not as robustly associated with efficacy as is the MIC of antibacterial drugs (Hussein et al., 2008a). Antiviral drugs tend to be narrow in spectrum with little cross-activity against multiple viruses. Another feature of antiviral agents that differs from that of antibacterial drugs is that only antiseptic and disinfectant agents can be classified as "virocidal" (antiseptics and disinfectants are discussed in Chapter 31 of this book), so antiviral drugs can only have virostatic actions, limiting replication until the host's immune system eliminates the viral infection. For this reason, antiviral drugs will be inactive against any nonreplicative or latent viral particles. This activity of antiviral drugs only against replicative virus also suggests why timing is critical to successful antiviral therapy, with early therapy resulting in optimal efficacy (Sawtell et al., 2001).

Antiherpesvirus Agents: Nucleoside Analogs

Acyclovir and Valacyclovir

Acyclovir (Zovirax®) is the prototypic nucleoside analog of the purine, deoxyguanosine. In veterinary medicine, the use of acyclovir is restricted to the therapy of herpesviruses. Acyclovir exemplifies selective activity against herpesviruses with little direct effect on host cells at therapeutic concentrations. This selectivity arises from the selective phosphorylation of acyclovir to its active form, acyclovir triphosphate, in infected cells. Acyclovir is monophosphorylated by viral thymidine kinase with 200 times greater efficiency than by the mammalian enzyme, which contributes to its favorable selectivity and high therapeutic index. Sequential phosphorylation by cellular and viral enzymes then form the triphosphate form, which selectively inhibits viral DNA polymerase by competing with deoxyguanosine triphosphate. Acyclo-GTP that is incorporated into viral DNA strands causes termination of elongation. Virally infected cells are 40–100 times more efficient in converting acyclo-GMP to acyclo-GTP than are noninfected cells. Penciclovir and ganciclovir (discussed in Section Penciclovir and Famciclovir and Section Cidofovir, Ganciclovir, and Valganciclovir) have similar mechanisms of action against herpesvirus. Valacyclovir is a prodrug that is itself inactive but is rapidly metabolized to its active form, acyclovir, after oral absorption. The presence of valine allows active transport of valacyclovir into enterocytes, with metabolism by plasma and hepatic esterases to acyclovir.

Spectrum of activity: Whereas herpes simplex viruses (HSV) of people are exquisitely sensitive to acyclovir, few herpesviruses of veterinary importance share this sensitivity. Feline herpesvirus type-1 (FHV-1) is only weakly susceptible to acyclovir with an IC_{50} of 58 μg/ml, more than 100 times higher than that of HSV-1 (Maggs and Clarke, 2004; Gaskell et al., 2007). In contrast, equine herpesvirus type-1 (EHV-1) shares a sensitivity to acyclovir that is similar to HSV, with an IC_{50} of 0.3–3 μg/ml (Wilkins, 2004; Garré et al., 2007b).

Pharmacokinetics: Pharmacokinetic data for acyclovir are available for horses, dogs, and cats, as well as Quaker parakeets, pheasants, and other species (de Miranda et al., 1982, 1981). Oral bioavailability of the drug is high in dogs (>80%), moderate in people (10–30%), but low and variable in horses (<5%). In dogs, oral absorption of acyclovir decreases with escalating doses (Krasny et al., 1981). In horses, the oral bioavailability was undetectable in one study (Wilkins et al., 2005), and only 2.8–4% in other studies (Garré et al., 2007a; Bentz et al., 2006). However, the elimination half-life of acyclovir administered intravenously to horses was reported as 5–53 hours. The high variability is attributed to sampling time and the study conditions (Garré et al., 2007a; Maxwell et al., 2008a). This equine elimination half-life was much longer than in other species (~2 hours in dogs and cats) and suggested the presence of a "deep compartment" in horses. The elimination half-life of acyclovir administered orally to pheasants was similar to that in dogs (3 hours), but was prolonged (15 hours) in box turtles after oral administration of valacyclovir (Rush et al., 2005; Allender et al., 2013). In the species in which mechanisms of clearance have been assessed, acyclovir was primarily eliminated via glomerular secretion (de Miranda et al., 1981, 1982; Krasny et al., 1981). An IV infusion of 10 mg/kg for 1 hour produced effective concentrations in horses for 8 hours and could be administered twice daily for EHV-1 (Wilkins et al., 2005). However, the IV route of administration is seldom used in veterinary medicine (see Section Adverse effects). Because the oral bioavailability of acyclovir is poor in most species, a much better absorbed valine ester prodrug, valacyclovir (Valtrex®), is preferred. In cats and horses, orally administered valacyclovir has much higher bioavailability (more than two times greater in cats; 6–15 times greater in horses) than does acyclovir (Garré et al., 2007a; Owens et al., 1996; Maxwell et al., 2008a).

Clinical use in cats: Clinical signs of herpesvirus infections (feline herpesvirus type-1, FHV-1) in cats prominently consist of upper respiratory disease and ocular lesions (Thomasy et al., 2007; and in review by Gaskell et al., 2007). Since the ocular lesions can progress from conjunctivitis to keratitis, it is the ocular form of the disease that generally warrants antiherpetic therapy. Since acyclovir is poorly absorbed and FHV-1 is relatively insensitive to acyclovir, high doses of valacyclovir were tested in cats in an experimental model of FHV-1. At a dose of 240 mg/kg/day of valacyclovir, nearly six times the maximum labeled dose in people, administration of valacyclovir to cats did not suppress FHV-1 replication but did produce signs of toxicity (Nasisse et al., 1997).

Clinical use in horses: Herpesvirus infections are also important in horses, where EHV-1 is associated with neonatal infections, respiratory disease, abortion, and myeloencephalopathy, depending on the age class of the horse. Oral acyclovir has been used as a treatment for neonatal disease and for equine herpesvirus myeloencephalopathy (EHM) (Murray et al., 1998; Friday et al., 2000). Acyclovir has also been administered to horses with multinodular pulmonary fibrosis (EMPF) attributed to EHV-5, although the sensitivity of EHV-5 to nucleoside analogs has not been determined (Wong et al., 2008). Although it is possible that oral acyclovir may accumulate with multiple doses and result in therapeutic concentrations for highly sensitive isolates associated with a slowly progressive disease such as EMPF, oral acyclovir is too low in horses to justify its use in rapidly progressing herpesvirus infections, such as EHM (Wong et al., 2010). Acyclovir may be more useful as a treatment of neonatal herpesvirus infection. In one herd outbreak of EHV-1 in foals, two of three foals treated with acyclovir survived, whereas the two foals not treated died (Murray et al., 1998). Since this disease is almost universally fatal in foals, acyclovir shows promise as a therapeutict agent.

For the treatment of EHV-1, therapeutic studies have tested the safety and efficacy of valacyclovir, which has been become a more economically feasible option in horses with the availability of generic tablets. Results of experimental trials of the use of valacyclovir against EHV-1 infection have been conflicting. Weanling ponies inoculated with EHV-1 showed neither signs of EHM nor reduction in viremia when valacyclovir was administered at 40 mg/kg every 8 hours for 5–7 days (Garré et al., 2009). However, aged mares appeared to have lower viral loads and be protected from EHM by valacyclovir administration early in the course of disease, at a loading dose of 36 mg/kg, oral, every 8 hours for 2 days, followed by a maintenance dose of 12 mg/kg every 12 hours for 7–14 days (Maxwell et al., 2008b, 2011).

Clinical use in psittacines: In birds, herpesvirus infections can be an important cause of morbidity. Acyclovir has been shown to decrease mortality in psittacine birds with herpesviral infections if the drug is administered prior to the onset of clinical signs (Smith, 1987). Orally administered acyclovir at 80 mg/kg IM every 24 hours after herpesvirus infection in Quaker parakeets was shown to be more effective in preventing death than either low- or high-dose (40 or 250 mg/kg) intramuscular injections. At the highest dose tested, acyclovir toxicity, as seen by local muscular necrosis, was thought to contribute to bird mortality (Norton et al., 1991). In pheasants, a dose of 120 mg/kg of acyclovir administered orally every 12 hours was necessary to maintain concentrations above 1.0 μg/ml, although the safety of this dose rate was not tested (Rush et al., 2005).

Adverse effects: The adverse effects of acyclovir and related drugs have not been well-documented in animals because of their infrequent use. Intravenous administration of acyclovir is seldom used in veterinary medicine due to cost and the increased risk of adverse effects that necessitate IV infusion over 1 hour to diminish the risk of presumed CNS effects (Bentz et al., 2006). Clinical signs of toxicity in cats that received high doses of valacyclovir included nephrotoxicity, as well as the bone marrow suppression that may have been an extension of pharmacological effects, since nucleoside analogs can inhibit cellular DNA replication at high enough concentrations (Nasisse et al., 1997). However, the reported renal tubular necrosis is a known adverse effect associated with high plasma concentrations of acyclovir and is attributed to crystalluria (Sawyer et al., 1988).

Penciclovir and Famciclovir

Penciclovir is administered topically as a 1% cream (Denavir®) for the therapy of herpes labialis in people. When considering the role of nucleoside analogs in veterinary herpesvirus infections, it is worth noting that efficacious topical penciclovir administration in people occurred with early therapy, beginning within 1 hour of lesion appearance, and with application every 2 waking hours. Even then, the main effect of penciclovir administration was to decrease the duration of clinical signs, rather than abolishing such signs. Penciclovir shares a similar mechanism of action as acyclovir, but the intracellular half-life in virus-infected cells is 10–20 times longer (Gill and Wood, 1996). This intracellular accumulation produces an indirect link between plasma penciclovir concentrations and its antiviral effect, and may also represent a therapeutic advantage of penciclovir as compared to acyclovir. Most HSV isolates are similarly sensitive to penciclovir and acyclovir, reflecting their similar mechanisms of action.

Spectrum of activity: As with acyclovir, HSV is quite sensitive to penciclovir, whereas FHV-1 is less so. However, FHV-1 is more sensitive to penciclovir than it is to acyclovir, with an IC_{50} of 3.2–10 μg/ml (Maggs and Clarke, 2004; Hussein et al., 2008b). With a reported IC_{50} of 1.6 μg/ml, EHV-1 may also be more sensitive to penciclovir than it is to acyclovir, although penciclovir sensitivity has been tested in only a single isolate (de la Fuente et al., 1992).

Pharmacokinetics: In rodents and people, the oral absorption of penciclovir is even lower than that of acyclovir. Therefore, an oral diacetate ester prodrug, famciclovir, was developed. It is more lipophilic than the active form, penciclovir, and has much greater oral bioavailability (Gudmundsson and Antman, 2007). After the oral administration of famciclovir to people and rodents, there is extensive metabolism by intestinal esterases and hepatic aldehyde oxidase to produce the active drug, penciclovir (Gudmundsson and Antman, 2007). When 62.5 mg famciclovir (~15 mg/kg) was orally administered to cats, plasma concentrations of penciclovir increased more slowly than in other species, were variable, and suggested saturable absorption (Thomasy et al., 2007). After oral absorption the elimination half-life of penciclovir in cats (3–4 hours) was similar to that of other species. Follow-up studies confirmed the variable and saturable absorption, as bioavailability fell from 12.5% at 40 mg/kg to 7% at 90 mg/kg (Thomasy et al., 2012b). Consequently, dose rates exceeding 40 mg/kg may not produce corresponding increases in plasma penciclovir concentrations. Nonetheless, maximal plasma penciclovir concentrations of 1.3 μg/ml in plasma and of 1.0 μg/ml in tear fluid demonstrated the feasibility of famciclovir administration to cats with ocular signs of FHV-1 infection (Thomasy et al., 2012a). The disposition of penciclovir following the oral administration of 20 mg/kg famciclovir to horses revealed maximal plasma penciclovir concentrations of 2.9 μg/ml, which was higher than in cats (Tsujimura et al., 2010). Interestingly, the elimination half-life of penciclovir after famciclovir administration to horses was prolonged (34 hours) as compared to other species, but similar to the prolonged elimination half-life of acyclovir after valacyclovir administration to horses (Maxwell et al., 2008a; Tsujimura et al., 2010). Despite the theoretical advantages of penciclovir as compared to acyclovir use in horses, studies of the efficacy of penciclovir or famciclovir in protecting horses from signs of EHV-1 or EHV-5 infection are not currently available.

Clinical use: At present, famciclovir is the only systemically administered antiviral agent that is routinely used in cats with ocular or upper respiratory signs of FHV-1 infection. Its efficacy was studied using an oral dose of 90 mg/kg every 8 hours, in cats experimentally inoculated with FHV-1 (Thomasy et al., 2011). In this model, disease score, conjunctivitis, and shedding of FHV-1 were all lower in the cats treated with famciclovir, supporting its clinical utility. However, a lower dose is more commonly used in clinical practice (Malik et al., 2009). It is available as 125, 250, 500 mg tablets, with one-quarter to one 125-mg tablet administered every 8–12 hours most often selected by clinicians. Given that famciclovir absorption profiles are not proportional to dose, it is unknown whether these lower dose rates are as efficacious as was reported experimentally for the high dose rate.

Adverse effects: Whereas one initial case series on the use of famciclovir in cats reported anorexia and polydipsia (Thomasy and Maggs, 2008), a follow-up study in which 90 mg/kg was administered every 8 hours reported no adverse effects (Thomasy et al., 2011).

Cidofovir, Ganciclovir, and Valganciclovir

Cidofovir was the first nucleoside analog approved for clinical use and is still used today as an injectable or ophthalmic implant formulation to treat cytomegalovirus infections in immunocompromised people. Cidofovir is more broadly active against a variety of DNA viruses than are the other nucleoside analogs, as it can be phosphorylated by cellular rather than viral enzymes. Since cidofovir accumulates intracellularly, with a prolonged intracellular elimination half-life, cidofovir can be administered less frequently than the other nucleoside analogs. Cross-resistance between cidofovir and other nucleoside analogs is also unlikely to occur since activation by viral enzymes is unnecessary for the activity of cidofovir. Ganciclovir is also a nucleoside analog but is more potent than acyclovir against herpesviruses, including FHV-1, EHV-1, and human cytomegalovirus (Maggs and Clarke, 2004). Ganciclovir is administered systemically as an injectable formulation for intravenous administration or as an oral tablet. Similar to acyclovir and penciclovir, ganciclovir is poorly absorbed after oral administration, so it has also been formulated as a valine ester prodrug to enhance oral absorption. Although valganciclovir is moderately well absorbed after oral administration to horses, the high cost of this prodrug has precluded further testing in this species (Carmichael et al., 2013). As with the other nucleoside analogs that have been studied in horses, the ganciclovir elimination phase is prolonged as compared to that of other species.

Clinical use: A 0.5% compounded topical formulation of cidofovir is used in cats with herpetic keratitis (Davidson, 2006). Cidofovir ophthalmic solution administered every 12 hours reduced ocular FHV-1 viral load in experimentally inoculated cats, supporting this less frequent dosing interval (Fontenelle et al., 2008). Ganciclovir is a first-line therapeutic agent for cytomegalovirus infections in people, since acyclovir and penciclovir are less potent and less efficacious against these viruses. Ganciclovir is similarly potent when tested in vitro against several herpesviruses of veterinary importance, including the zoonotic, Monkey B virus, endemic to macaques (Brush et al., 2014). Ganciclovir has also been administered intravenously to horses at later stages of infection with EHV-1, when valacyclovir administration may be ineffective (Maxwell et al., 2011).

Adverse effects: Nephrotoxicity is the dose-limiting side effect associated with parenteral cidofovir administration, necessitating coadministration with probenecid to spare the kidneys. Therefore, parenteral cidofovir is not used clinically in veterinary species. However, ophthalmic administration of 0.5% cidofovir appears to be well-tolerated in cats (Fontenelle et al., 2008). Although ganciclovir is more potent than the other antiherpetic guanine analogs, it also has a narrower therapeutic index. Reversible bone marrow suppression, with neutropenia, thrombocytopenia, and anemia, can occur in people that require intravenous doses of ganciclovir, whereas temporary or permanent impairment of fertility as well as teratogenesis occurred in laboratory animals treated with ganciclovir for a prolonged period of time. When administered to mares at a maintenance dose of 2.5 mg/kg every 12 hours for 1 week, side effects were not noted (Maxwell et al., 2011).

Idoxuridine and Trifluridine

Idoxuridine (5-iodo-2′-deoxyuridine, formerly Herplex®, Stoxil®) and trifluridine (5-trifluoromethyl-2′-deoxyuridine, Viroptic®) are thymidine analogs that are only active against DNA viruses, primarily herpesvirus and poxvirus. Like other nucleoside analogs, the compounds are phosphorylated inside the host cell and then incorporated into growing mammalian and viral DNA strands. Only trifluridine is commercially available as a topical ophthalmic preparation for the treatment of herpetic keratitis. The commercial formulation for idoxuridine was withdrawn and is now only available as a compounded solution (0.1%) or ointment (0.5%). Trifluridine (also known as trifluorothymidine) is thought to have higher affinity for viral DNA than mammalian, and so is more potent; however, it also causes the most conjunctival irritation in vivo (Nasisse et al., 1989). Since idoxuridine is better tolerated by cats with herpetic keratitis, it is the more popular choice (Stiles, 1995). As with most other antiherpetic drugs, antiviral effects do not persist once the drug is eliminated from the eye, so the ophthalmic preparations must be applied multiple times per day. Neither drug is administered systemically due to their propensity for toxic side effects.

Cytarabine and Vidarabine

Cytarabine (Ara-C® also known as cytosine arabinoside) and vidarabine (Ara-A®), are nucleoside analogs of cytosine and adenine, respectively. They have in vitro activity against certain DNA viruses, including herpesviruses, poxviruses, vaccinia, rabies, cytomegalovirus, and probably hepatitis B virus. Cellular enzymes convert these compounds to the triphosphate form, which then act as competitive inhibitors of DNA polymerase. As with other antiherpetic drugs that are activated by cellular rather than viral enzymes, cytarbine and vidarabine are not very selective in their activity. As a result, side effects of these drugs have limited the clinical utility of parenterally administered formulations in both humans and veterinary species. Cytarabine is used as an antineoplastic agent in dogs and cats for treatment of leukemia and lymphoma. Its use as an anticancer drug is discussed in more detail in Chapter 44. Cytarabine also is used to treat meningoencephalomyelitis in dogs and is administered either subcutaneously or intravenously (Crook et al., 2013).

Vidarabine is no longer commercially manufactured in the USA, but is occasionally used topically as a compounded 3% ointment in the treatment of herpetic keratitis, although it is less potent against feline herpesviruses than is idoxuridine or trifluridine (Nasisse et al., 1989). The main advantage of vidarabine over the other antiherpetic agents discussed is that viral isolates may not be cross-resistant to both idoxuridine and vidarabine (Eriksson and Oberg, 1979).

Ribavirin

Ribavirin (Virazole®) is a guanosine analog that inhibits the replication of a wide range of RNA and DNA viruses in vitro (Te et al., 2007). In human medicine, ribavirin is primarily used in the therapy of selected RNA viruses, including hepatitis C, respiratory syncytial virus, Lassa fever virus, and influenza A and B. Ribavirin is thought to have multiple sites of action. After being monophosphorylated to ribavirin 5′-monophosphate by adenosine kinase, further phosphorylation to ribavirin 5′-triphosphate predominates intracellularly, and competitively inhibits RNA polymerase and viral replication. Most of the studies investigating the utility of ribavirin against veterinary diseases have been disappointing. Oral ribavirin worsened the condition of cats experimentally infected with calicivirus. Bone marrow suppression, weight loss, increased hepatic enzymes, and icterus were seen (Povey, 1978). These side effects were also seen in healthy cats given the drug (Weiss et al., 1993a); however, they were not seen in dogs when given 60 mg/kg for 2 weeks (Canonico, 1985). Ribavirin was shown to have in vitro antiviral activity against the feline infectious peritonitis (FIP) virus at concentrations of 150 μg/ml (Barlough and Scott, 1989). However, kittens experimentally infected with FIP virus had no significant difference in outcome when compared to those treated with placebo (Weiss et al., 1993b). In fact, similar to the cats infected with calicivirus, the ribavirin-treated FIP kittens had a worsening of clinical signs. In vitro activity against various viral pathogens, including bovine rhinotracheitis and bovine viral diarrhea has also been demonstrated, but there are no reports of the use of this compound in infected animals (Glotov et al., 2004). As is the case with the therapy of hepatitis C infections in people, the efficacy of ribavirin may be enhanced when interferons are coadministered (Carvalho et al., 2014).

Zidovudine, PMEA, and Lamivudine

Zidovudine (Azidothymidine®, AZT®, Retrovir®) is a thymidine analog that was key to the early antiviral success against human immunodeficiency virus (HIV). As such, AZT is a nucleotide analog that selectively inhibits viral reverse transcriptase (nucleoside reverse transcriptase inhibitor, NRTI), preventing viral RNA from making a DNA copy of itself. Like the nucleoside analogs discussed above, AZT is phosphorylated by cellular enzymes to the active triphosphate form. AZT inhibits the viral enzyme with greater affinity (~100 times) than mammalian DNA polymerases, resulting in selective activity and low mammalian toxicity. Adefovir (PMEA) is an acyclic purine nucleoside analog that is used in the therapy of hepatitis and herpesviruses in people, but has been investigated as an antiretroviral drug in cats. Lamivudine is also an older NTRI that has been similarly investigated in cats.

AZT can be given orally or IV in humans. Its oral bioavailability is 60–65%, and peak concentrations are achieved in about 1 hour. AZT is quickly metabolized to the 5′glucuronide, and both the metabolite and parent compound are eliminated in urine with a half-life of approximately 1 hour. The pharmacokinetics of AZT at a dose of 25 mg/kg have been studied in cats following IV, PO, or intragastric (IG) administration through a gastrostomy tube (Zhang et al., 2004a). Absorption following PO administration (95%) was higher than IG administration (70%), but effective plasma concentrations, as determined by the in vitro EC_{50}, were maintained for at least 12 hours following administration by all three routes. As in people, the elimination half-life was short (1.4 hours). No adverse effects, other than hemolysis after

IV injection, were observed in this study; however, only single doses were administered. These same investigators also studied the pharmacokinetics of lamivudine in cats (Zhang et al., 2004b). The pharmacokinetics were similar to those of AZT in cats, but with a high bioavailability, short half-life, and plasma concentrations maintained above the predicted EC_{50} for 12 hours following either IV, PO, or IG dosing of 25 mg/kg.

Clinical use: The use of AZT has been investigated in cats both as a clinical therapeutic and experimentally, using FIV as an animal model of HIV infection. Reverse transcriptase from FIV and HIV-1 viruses was shown to be nearly identical in sensitivity to several antiviral agents, including AZT. In addition, similar concentrations of AZT were required to inhibit replication of these viruses (North et al., 1989). Bovine leukemia virus has also been suggested as a possible animal model for investigation of retroviral infection. AZT inhibition of bovine leukemia virus reverse transcriptase was similar to that of FIV-RT (Reimer et al., 1989).

In experimental FeLV infections, when treated with high doses (20 mg/kg every 8 hours) of AZT within 1 week after virus challenge, kittens were protected from bone marrow infection and viremia. Administration of AZT did not eliminate viremia in kittens if treatment was delayed to 1 and 3 weeks after FeLV inoculation; however, antigen load in the blood was reduced (Tavares et al., 1987). AZT alone, or in combination with interferon or interleukin, was shown to prevent infection in cats challenged with virulent FeLV virus for a period of 6 weeks (Zeidner et al., 1989). However, in cats experimentally inoculated with FIV, even prophylactic use of high doses of AZT did not adequately protect cats from infection (Smyth et al., 1994). PMEA has been studied in the treatment of both FeLV and FIV infections in cats. PMEA was found to inhibit replication of FeLV in vitro and prevented the development of persistent antiginemia and the induction of the immunodeficiency disease in cats inoculated with the virus (Hoover et al., 1991).

AZT has been shown to reduce clinical signs when given to two FIV-positive cats at a dose of 10 mg/kg twice a day subcutaneously for a period of 3 weeks (Egberink et al., 1991). Although it did not eradicate the infection, the authors suggest it is of clinical benefit. Currently, AZT is primarily used to improve clinical signs, such as stomatitis, of cats with FIV and FeLV (Hartmann et al., 1992). In order to reduce dose-limiting side effects, a dose rate of 5 mg/kg PO every 12 hours has been used in symptomatic cats, although efficacy in cats naturally infected with FeLV was not documented (Stuetzer et al., 2013). Seropositive cats with symptoms of opportunistic infection showed improvement of clinical signs during PMEA therapy at 5 mg/kg/day (Egberink et al., 1990). A comparative study on the effects of PMEA and AZT on FIV- or FeLV-positive cats showed that PMEA was superior to AZT in diminishing the clinical signs of disease (Hartmann et al., 1992).

Overall, clinical utility of NRTIs in the therapy of retroviral infections in cats has been disappointing, with only moderate suppression of FeLV and FIV viral loads when therapy is initiated after the infection has become established. Although dose-limiting side effects may partially explain this suboptimal control of retroviral replication, there are also key differences between the much more successfully therapy of HIV in people and the therapy of retroviral diseases in cats. In people, AZT is always combined with other drugs, from a list of 25 antiretroviral drugs in six mechanistic classes, resulting in highly effective antiretroviral therapy (HAART) protocols that are tailored to the needs and responses of individual patients (Panel on Antiretroviral Guidelines for Adults and Adolescents, 2015). Multiple drug protocols are always used to prevent the development of resistance to a single mechanistic class. Monotherapy in cats with AZT or AZT in combination with an immunomodulator, combined with dose-limiting side effects in cats, may limit the ability of antiretroviral therapy to successfully manage FeLV and FIV. Safe and effective combination antiretroviral therapy has not been established in cats. In vitro, lamivudine is synergistic in combination with AZT against FIV, but in chronically infected, experimental cats, the combination did not reduce FIV load and severe side effects were observed (Arai et al., 2002).

Adverse effects: Major toxicities of AZT include anemia and granulocytopenia, which occur in up to 45% of treated human patients (Richman, 1987). Dose escalation studies have demonstrated a dose-dependent and progressive anemia and neutropenia in cats chronically administered >30 mg/kg/day PO divided into three doses for 32–34 days. Marked bone marrow hypercellularity and extramedullary hematopoeisis were observed on postmortem examination (Haschek et al., 1990). In feline patients, Heinz body anemia is the major side effect observed with long-term AZT administration (Hart and Nolte, 1993). When AZT and lamivudine were coadministered to cats at high dose rates, some cats had severe hematological side effects and fevers (Arai et al., 2002). Although PMEA seemed to be more efficacious than AZT in feline patients, the adverse effects (mainly hematological) were more severe with PMEA, limiting its use (Hartmann et al., 1992).

Oseltamivir

Oseltamivir phosphate (Tamiflu®) is an ester prodrug that is converted by hepatic esterases to its active metabolite, oseltamivir carboxylate. In people, only a small percentage of oseltamivir phosphate reaches the systemic circulation, whereas approximately 75% of the oral dose appears in systemic circulation as the active metabolite. Unlike the antiherpetic and antiretroviral drugs discussed above, oseltamivir does not act by directly inhibiting viral replication. Instead, oseltamivir is a competitive inhibitor of the enzyme neuraminidase, which influenza viruses use as part of the process of budding of the replicative viral particles from infected cells. The in vitro efficacy of oseltamivir has been tested against twelve strains of equine influenza A virus (EIV), and most isolates were quite sensitive at IC_{50} concentrations of 4.3–27.5 ng/ml (Yamanaka et al., 2006a). However, one isolate exhibited a much higher IC_{50} of 3785 ng/ml, demonstrating the variability in antiviral susceptibility among influenza strains. Although bioavailability was not determined, when 2 mg/kg of oseltamivir phosphate was administered orally to horses, the resulting plasma concentrations of oseltamivir carboxylate were similar to the plasma concentrations associated with a similar dose in people (Yamanaka et al., 2007). As in people, oseltamivir carboxylate is rapidly eliminated in horses, with a mean elimination phase half-life of 2.5 hours. Given that rapid rate of elimination, the dosing interval of oseltamivir administration in horses may need to be less than 10 hours.

Clinical Use

The efficacy of oseltamivir administered at a dose rate of 5 mg/kg twice daily for 5 days was investigated in a small group of horses experimentally inoculated with EIV (Yamanaka et al., 2006b). Although the small size of the study prevented definitive assessment of drug efficacy, oseltamivir administration did appear to decrease viral shedding, fever, and secondary bacterial pneumonia. Although there is interest in using oseltamivir in recent outbreaks of dogs infected with a canine influenza virus (CIV) that is apparently related to EIV, evidence for its efficacy against CIV is primarily anecdotal. As with most antiviral drugs, the timing of oseltamivir administration is critical to therapeutic outcome in people and must usually be initiated within 48 hours of illness (Rodriguez et al., 2011). Such early initiation of therapy is unlikely in a clinical veterinary setting. Since oseltamivir is an important component in the arsenal against influenza virus infections in people, and resistance to this and other drugs active against influenza can develop rapidly, reserving oseltamivir for human use may be the most prudent approach (Cheng et al., 2010). Indeed, due to concerns regarding pandemic avian influenza virus becoming resistant to oseltamivir (Lee et al., 2011), neuraminidase inhibitors are prohibited by the FDA for extralabel drug use in poultry. Although oseltamivir is not widely used in the therapy of CIV or EIV, it has been used with some regularity in the USA for the therapy of parvovirus infections in dogs. Since parvovirus does not use neuraminidase, the proposed rationale for therapy has instead centered on inhibition of secondary bacterial infections subsequent to parvovirus infections. A clinical trial was performed to test whether addition of oseltamivir at a dose rate of 2 mg/kg PO every 12 hours to a standard protocol improved outcomes in 19 dogs with parvovirus as compared to 16 dogs in the control group (Savigny and Macintire, 2010). Addition of oseltamivir to standard therapy did not affect disease scores, hospitalization time, or mortality, but treated dogs did lose less weight than control dogs and had a less profound decrease in circulating leukocytes. Given that the mechanism of action of oseltamivir does not support efficacy against parvovirus, only a small difference in outcome was associated with oseltamivir therapy, and public health concerns about spread of drug-resistant influenza from dogs to people, oseltamivir use in this setting is difficult to justify.

Adverse Effects

In people, gastrointestinal irritation is the most common side effect associated with oseltamivir administration. Nausea and vomiting have also been observed in dogs during administration of oseltamivir, although this effect may be minimized by dilution of the oseltamivir suspension (Savigny and Macintire, 2010). Side effects were not reported when a similar dose rate of oseltamivir was administered to horses (Yamanaka et al., 2006b).

Amantadine and Rimantadine

Amantadine hydrochloride (1-adamantanamine hydrochloride, Symmetrel®) and rimantadine (Flumadine®) are water-soluble cyclic amines with antiviral activity against a narrow range of RNA viruses, including myxoviruses, paramyxoviruses, togaviruses, and most strains of influenza A virus. Rimantadine has approximately three to four times greater in vitro activity against influenza A than amantadine (Betts, 1991). The mechanism of these two related compounds has been debated. They were thought at one time to prevent viral penetration and uncoating, but this was later refuted (Couch and Six, 1986). Their antiviral activity is now thought to involve inhibition of late-stage assembly of the virus.

Experimentally infected chicks that received amantadine via the drinking water were one-half as likely to die as untreated controls (Obrosova-Serova et al., 1976). However, the use of amantadine in poultry is thought to be responsible for the amantadine resistant influenza strains seen in the Chinese pandemic in 2005 (Ilyushina et al., 2005). Therefore, the FDA now prohibits the extralabel drug use of amantadine and rimantadine in poultry. These two compounds have been investigated for the treatment of influenza in the horse. In vitro testing suggests that amantadine suppresses viral replication at concentrations of 300 ng/ml while rimantadine is more potent and has activity at concentrations as low as 30 ng/ml (Rees et al., 1997, 1999). Amantadine caused serious adverse effects, including fatal seizures, in horses at doses of 10–15 mg/kg IV. Absorption of the drug following oral administration was highly variable between individual horses; therefore, a dose could not be recommended (Rees et al., 1997). Rimantadine shows greater promise as an antiviral drug in horses. A multiple dose study examining the effects of oral rimantadine at a dose of 30 mg/kg q 12 h showed adequate absorption of the drug with plasma concentrations maintained above the estimated effective concentration (30 ng/ml) throughout the dosing interval. No side effects were reported. In challenge studies using influenza virus A2, prophylactic rimantadine administration caused a significant decrease in rectal temperature and lung sounds (Rees et al., 1999). However, both amantadine and rimantadine have fallen out of favor for the treatment of influenza in people. Although amantadine and rimantadine were originally introduced as antiviral agents, their poor efficacy in human influenza patients and the likelihood of adverse effects, such as gastrointestinal irritation and central nervous system effects, has resulted in recommendations against their use for influenza virus (Jefferson et al., 2006).

Treatment of Pain

An additional use of amantadine is for treatment of pain syndromes in animals. The proposed mechanism of action for amantadine is via inhibiting the neurotransmitter *N*-methyl-ᴅ-aspartate (NMDA) (Pozzi et al., 2006). NMDA produces central sensitization and pain in animals. Blocking of the NMDA central receptor by amantadine has been associated with relief of pain syndromes. Amantadine is well absorbed orally in practically all animals, but the precise duration of action and dosing regimens have not been fully investigated in animals. In one study, amantadine was administered for 21 days, in combination with meloxicam, for the alleviation of refractory osteoarthritis pain in dogs (Lascelles et al., 2008). At a dose of 3–5 mg/kg orally, once daily, with meloxicam, dogs responded better than if administered meloxicam alone. Other doses that have been cited for pain are 2–10 mg/kg orally every 8–12 hours in dogs and 2 mg/kg orally every 24 hours in cats (Pozzi et al., 2006).

Interferon

A complete discussion of the biochemistry, physiology, and immunological function of interferon-$\alpha_{2a,2b}$ (Roferon-A, Intron A) is beyond the scope of this chapter. Interferons are polypeptide molecules produced by certain mammalian cells in response to viral infections as well as other stimuli. They are potent cytokines that possess antiviral, immunomodulating, and anticancer properties (Pestka et al., 1987). Interferons are divided into three types: type I, which includes IFN-α, IFN-β, and IFN-ω, type II, composed of only IFN-γ, and type III, which are the IFN-λs (Hoffmann et al., 2015). The antiviral activities of interferons are indirect. They induce a variety of antiviral mechanisms via enhancement of IFN responsive gene promoters within the host cells. An interesting property of IFNs is that once they induce an antiviral state in one cell, that cell can then transfer this antiviral activity to other cells through cell-to-cell contact without requiring additional IFN. This has been demonstrated in vivo using IFN-α stimulated lymphocytes. This results in an amplification of the antiviral effect, which may explain why IFNs are efficacious despite low to undetectable plasma levels (Stanton et al., 1989). Some interferons are highly conserved between species and therefore their actions are not species specific. In people, multiple interferons have been used for treatment of HIV and cancer-associated diseases.

Interferons have been administered parenterally, intranasally, and orally. Parenteral and intranasal administration lead to an increased risk of adverse effects, including formation of neutralizing antibodies to IFN, as well as clinical signs of hyperthermia, anorexia, and malaise (Roney et al., 1985). Being peptides, interferons are inactivated by the digestive enzymes in the gastrointestinal tract, yet orally administered IFN has been shown to be an effective treatment for viral diseases in a number of species (Cummins et al., 1999). The probable mechanism for this is uptake of IFN by the oropharyngeal-associated lymphoid tissue, which sensitizes the lymphocytes in these organs. The lymphocytes are then released into the circulation where they can confer antiviral activity to cells at the site of infection (Bocci, 1991).

Alpha Interferon

In vitro studies have demonstrated that FHV-1 is susceptible to feline interferon (IFN-ω) or human IFN-α (Siebeck et al., 2006). Interferons and antiviral drugs, such as acyclovir, can act synergistically to inhibit viral replication (Weiss, 1989). The human formulation of IFN-α is available as an injectable formulation, but it has been administered in an extralabel manner by both oral and parenteral routes to veterinary species. Surprisingly, a dose as low as 0.5 U administered PO to cats appears to exert antiviral activity (Cummins et al., 1988). However, oral administration of IFN-α to horses at doses of 0.22 to 2.2 U/kg just before and after inoculation with EHV-1 failed to produce a protective response (Seahorn et al., 1990). Most of the use of IFN-α has been

Table 38.6 Clinical and experimental uses of interferon in veterinary species

Species	Disease treated	IFN Subtype	Dose and route of administration	Results	Reference
Feline	FeLV	Human IFN-α	1.6×10^4–1.6×10^6 U/kg with or without AZT at 10 mg/kg q 8 h	IFN administration decreased p27 antigen, but cats became refractory in 3–7 weeks, whereas AZT had no effect	Zeidner et al., 1990
	FIP (coronavirus)	Recombinant feline IFN-γ	1 million U/kg SC EOD until remission followed by weekly injections of the same dose	Produce complete remission (>2 years) in 4/12 cats, and partial remission (2–5 months) in 4/12 cats; only cats with the effusive form of FIP responded.	Ishida et al., 2004
	FeLV or FeLV/FIV coinfection	Recombinant feline IFN-ω	1 million U/kg SC q24h for 5 consecutive days in 3 series (day 0, 14, and 60)	Placebo controlled study; treated cats had significantly lower clinical scores in the first 4 months and significantly lower mortality rates at 9 and 12 months.	de Mari et al., 2004
	FeLV	Human IFN-α with or without *Staphylococcus* Protein A (SPA)	30 U/cat PO once daily on weeks 1,3,5,7, and 9	Placebo controlled study; no significant improvements seen in animals treated with IFN compared to controls; mild improvement noted based on owner perception in cats treated with SPA alone.	McCaw et al., 2001
	FIV	Natural human IFN-α	10 IU/kg PO q24h on alternating weeks for 6 months	Treated cats had a significant improvement in clinical signs and a longer survival than controls; no correlation with plasma viremia or viral load in leukocytes was noted.	Pedretti et al., 2005
	FeLV, FIV	Recombinant feline IFN-ω	1 million U/kg SC q24h for 5 consecutive days in 3 series (day 0, 14, and 60)	Cats treated with IFN had better improvement in clinical scores as compared with control cats, but proviral load and viremia were not affected.	Domenech et al., 2011
	FeLV	Human IFN-α	$1\text{x}10^5$ U/kg with or without AZT at 5 mg/kg q 12 h	No significant differences between placebo control and drug treatment groups in p27 antigen.	Stuetzer et al., 2013
Canine	Parvovirus (CPV-2)	Recombinant feline IFN-ω	1 million U/kg IV q24h for 3 consecutive days starting 4 days after viral inoculation	Placebo controlled study; treatment significantly reduced the severity of the enteritis within 12 hours of administration of the first dose; all dogs received standard supportive therapy.	Ishiwata et al., 1998
	Parvovirus	Recombinant feline IFN-ω	2.5 million U/kg IV q24h for 3 consecutive days	Multicentric, double-blind, placebo controlled field trial; treated dogs showed a significant improvement in clinical signs; mortality rate was 7% in treated dogs and 29% in controls; all dogs received standard supportive therapy.	de Mari et al., 2003

(*continued*)

Table 38.6 (*Continued*)

Species	Disease treated	IFN Subtype	Dose and route of administration	Results	Reference
Bovine	Vaccinia (Smallpox)	Natural human IFN-α2	10 million U/kg IM q24h starting 24 hours prior to viral inoculation	Placebo controlled study; complete protection was obtained at this dose.	Werenne et al., 1985
	IBR	Recombinant human IFN-α	0.05–5 U/kg PO q24h for 4 days starting 48 hours prior to intranasal viral inoculation	Placebo controlled study; the 0.05 and 0.5 U/kg groups showed significant improvement in mean rectal temperature and duration of antibiotic therapy; the 0.05 U/kg group also had significantly better weight gain.	Cummins et al., 1993
	IBR	Recombinant bovine IFN-α1	10 mg/animal intranasally 48 hours prior to viral inoculation	Significant reduction in morbidity and mortality in treated animals was noted, although treatment did not prevent clinical signs or affect viral shedding.	Babiuk et al., 1987
	BLV	Recombinant bovine IFN-τ	10^5–10^6 U/kg SC 3x/week for 3–4 weeks	Reduced titers of BLV in IFN treated cattle	Basu et al., 2006
	BVDV	Recombinant bovine IFN-τ	10^5–10^6 U/kg SC 5x/week for 2 weeks	Serum titers to BVDV decreased slightly in the high dose group, but only during the administration period	Kohara et al., 2012
Swine	FMDV	Adenovirus expressing porcine IFN-α or IFN-γ, alone and in combination	Low and high doses of each cytokine	Swine with the combination of the two IFNs were completely protected from challenge infection, in contrast to control animals	Moraes et al., 2007
Equine	EHV-1	Recombinant human IFN-α2a	0.22 or 2.2 U/kg PO 48 and 24 hours prior to viral inoculation and 24 hours after inoculation	No significant effects on clinical disease or duration of viral shedding were noted.	Seahorn et al., 1990
	Inflammatory airway disease	Recombinant and natural human IFN-α	90 U/horse (recombinant) or 50 U/horse (natural) PO q24h for 5 days	Placebo controlled study; all horses had a significant decrease in cough and nasal discharge; significantly fewer horses treated with either IFN product had a relapse after 4 weeks; viral etiology in this disease not proven.	Moore et al., 2004
	Shipping fever	Human IFN-α	1.25 g/head PO q24 h for 4 days	Placebo controlled study; elevations in white blood cells, fibrinogen, serum amyloid A were partially mitigated by IFN administration.	Akai et al., 2008

BLV, bovine leukemia virus; BVDV, bovine viral diarrhea virus; CPV, canine parvovirus; EHV, equine herpesvirus; FeLV, feline leukemia virus; FIP, feline infectious peritonitis; FMDV, foot-and-mouth disease virus; IFN, interferon; IBR, infectious bovine rhinotracheitis.

in experimentally infected animals or anecdotal, with few clinical trials to demonstrate efficacy for treating FHV-1 infections (Gaskell et al., 2007).

Omega Interferon

Omega interferons are licensed for use in the treatment of viral disease of dogs and cats in Europe, Japan, Australia, New Zealand, and Mexico. Omega interferon of feline origin, produced by genetic engineering, is a type 1 interferon closely related to α-interferon (Yang et al., 2007). This IFN-ω binds to the same receptors as IFN-α and IFN-β. Recombinant IFN-ω contained in Virbagen Omega is produced by silkworms previously inoculated with interferon-recombinant baculovirus, resulting in the synthesis of pure interferon.

After injection, IFN-ω has a half-life of 1.4 hours in dogs and 1.7 hours in cats. The IFN-ω is rapidly cleared by the kidneys and is not widely distributed. Instead, it is bound to receptors in cells infected by virus. Interferon has been used to stimulate immune cells in dogs with parvovirus and in cats with feline retrovirus (FeLV and FIV), which are the labeled indications for Virbagen Omega.

Doses and indications for animals have primarily been based on extrapolation of human recommendations, experimental studies in animals, or specific studies in cats and dogs with viral infections. The formulation used in veterinary medicine is available in 5 and 10 million units/vial, which is reconstituted before use. The suggested dose in dogs is 2.5 million units (MU)/kg IV once daily for 3 consecutive days. The dose in cats is 1.0 MU/kg SC for 5 consecutive days. Three separate 5-day treatments must be performed at day 0, day 14, and day 60. A summary of some of the reports of interferon use in natural and experimental viral disease of different species is presented in Table 38.6.

Adverse reactions: In people, injections of IFN-α have been associated with influenza-like symptoms. Other effects also have been reported in people, such as bone marrow suppression. In animals, interferon has been generally well tolerated, but may induce vomiting and nausea. In some animals it may induce hyperthermia 3–6 hours after injection. In cats, it may produce soft feces to mild diarrhea. A slight decrease in white blood cells, platelets, and red blood cells, and rise in the concentration of alanine aminotransferase may be observed. These parameters usually return to normal in the week following the last injection. In cats, it may induce transient fatigue during the treatment. Do not vaccinate dogs or cats receiving interferon.

L-Lysine

L-lysine is an essential amino acid that blocks the availability of arginine, which is necessary for the replication of herpesviruses. In vitro testing has demonstrated an inhibitory effect of L-lysine on FHV-1 replication in the presence of arginine (Maggs et al., 2000). Additionally, a dose of 400 mg per day, given in food, reduced viral shedding following the stress of changes in housing and husbandry (Maggs et al., 2003). This beneficial effect was blocked when the cats were given methylprednisolone to induce viral shedding. When given prophylactically at a dose of 500 mg 6 hours prior to viral challenge, and then continued at 500 mg PO q 12 h, it decreased the severity of the ocular lesions compared to controls; however, it had no effect on virus isolation (Stiles et al., 2002). Despite the promising results cited above, clinical results have been disappointing. A clinical study in shelter population cats did not show a benefit of treatment (Rees and Lubinski, 2008). When 144 treated shelter cats were compared to 147 controls, there was no difference in prevention of upper respiratory infection or conjunctivitis when cats were supplemented with 250 or 500 mg daily oral L-lysine. There was actually an increase in severity of some infections. For these reasons, the use of L-lysine to treat FHV-1 in shelter cats is not recommended until reevaluation is available.

Chemotherapy of Parasitic Diseases

39

Antinematodal Drugs

Carlos E. Lanusse, Juan M. Sallovitz, Sergio F. Sanchez Bruni, and Luis I. Alvarez

The economic importance of helminth infections in livestock has long been recognized and it is probably for this reason that the most important advances in the chemotherapy of helminthiasis have come from the animal health area (Horton, 1990). Anthelmintics are used in all animal species and man. A significant part of the economic impact of parasitism in animal production is represented by the investment in control measures. Although alternative methods have been developed, chemically based treatments are the most important tool to control parasitism. A more complete understanding of the pharmacological properties of existing antiparasitic drugs should assist with more efficient parasite control both in livestock and companion animals. However, the investment in control measures does not always result in the expected therapeutic success. Among factors responsible for that therapeutic failure are: (i) inadequate integration between management strategies and chemotherapy; (ii) incorrect use of anthelmintic drugs due to insufficient knowledge of their pharmacological features; and (iii) insufficient understanding of the relationship between pharmacological properties and several host-related factors that could lead to modifications of the pharmacokinetic behavior and to a decreased antiparasite efficacy of the chosen drug. In addition, the availability of many compounds with a common mode of action and the indiscriminate use of these drugs have accounted for the widespread development of drug resistance, mainly in parasites of sheep and goats, but also in parasites of pigs, horses, and cattle. This chapter covers the information available for the different specific antinematodal drug families used in veterinary therapeutics. However, special consideration is given to the description of the large body of pharmacological knowledge generated for the benzimidazole compounds, the most intensively studied anthelmintic chemical group together with the endectocide macrocyclic lactones (see Chapter 41).

Benzimidazoles and Probenzimidazoles

Benzimidazoles (BZD) and pro-benzimidazoles (pro-BZD) anthelmintics are widely used in veterinary and human medicine. The pro-BZD are inactive prodrugs metabolically converted into anthelmintically active BZD molecules in the host. The remarkable overall safety of BZD compounds has been a major factor in their successful worldwide use over four decades. BZD were introduced into the animal health market primarily for the control of gastrointestinal (GI) nematodes, not only for use in livestock animals (cattle, sheep, goats, swine, and poultry), but also for horses, dogs, and cats. The use of BZD compounds quickly became widespread because they offered major advantages over previously available drugs in terms of spectrum, efficacy against immature stages, and safety for the host animal.

Chemistry

Since the discovery of thiabendazole in 1961 (Brown et al., 1964), several thousand BZD molecules have been synthesized and screened for anthelmintic activity. However, no more than 20 of them have been commercially developed for use in domestic animals and man, either as BZDs or pro-BZDs. The BZD structure is a bicyclic ring system in which benzene has been fused to the 4- and 5- positions of the heterocycle (imidazole) (Figure 39.1). Most of the BZD compounds are white crystalline powders, with fairly high melting point and insoluble or slightly soluble in water. Their aqueous solubility is markedly higher at low acidic pH values, with the stomach/abomasum being the appropriate site for the dissolution of BZD drug particles after oral treatment. The BZD compounds can be grouped as follows:

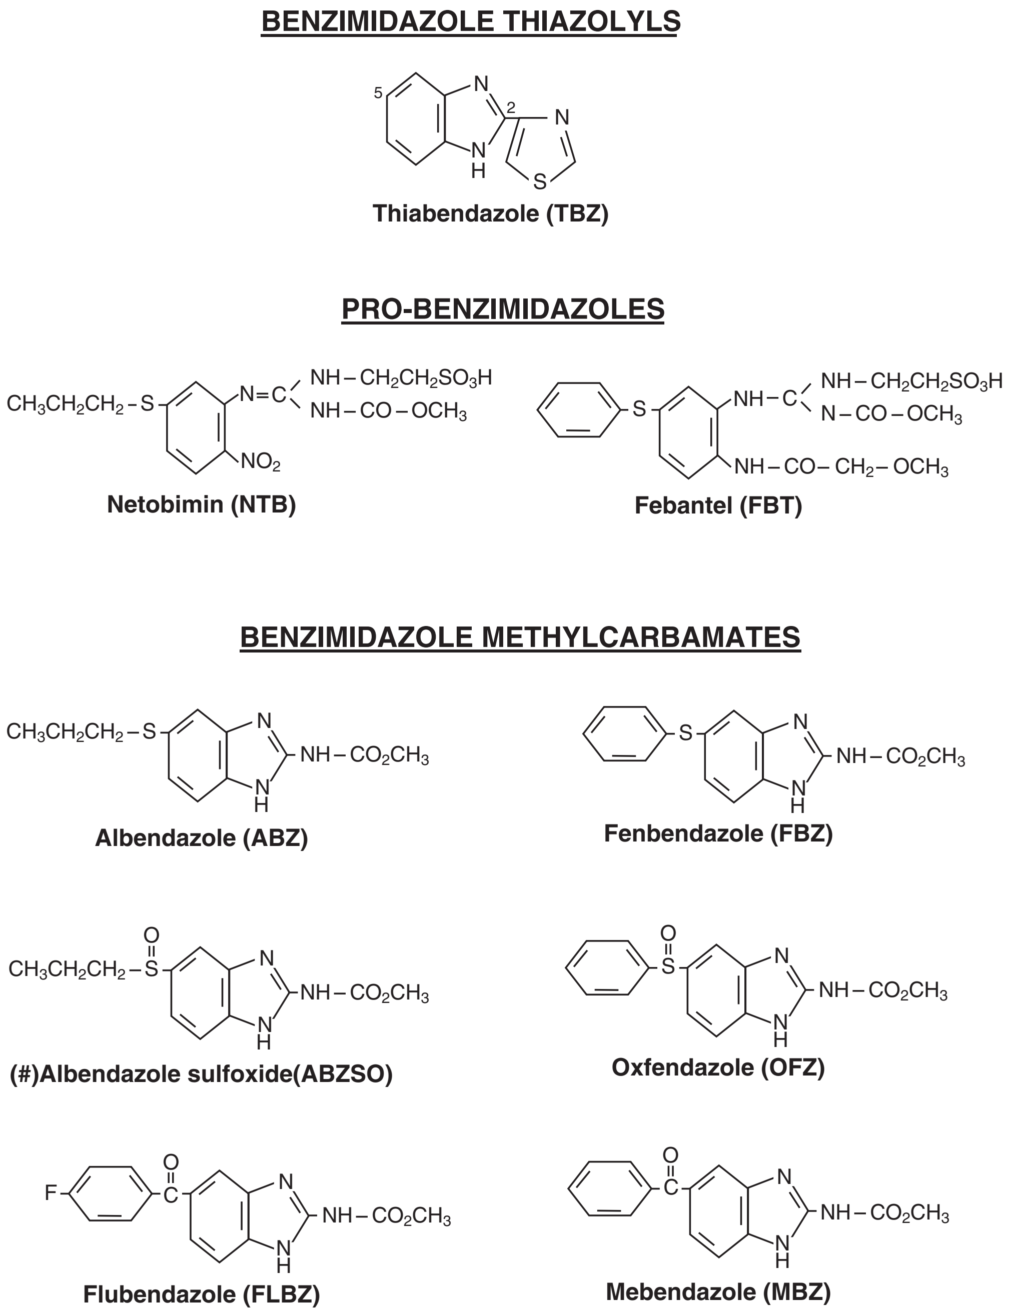

Figure 39.1 Chemical structures of the main benzimidazole (BZD) anthelmintics used in veterinary medicine. The positions 2- and 5- (main substitution sites) are shown in the thiabendazole structure. (#) ABZSO is also known as ricobendazole (RBZ). Triclabendazole (a halogenated flukicidal BZD) is not included here (see Chapter 40).

1) *BZD thiazolyls*: thiabendazole, cambendazole;
2) *BZD methylcarbamates*: parbendazole, mebendazole, flubendazole, oxibendazole, luxabendazole, albendazole, albendazole sulfoxide, also known as ricobendazole, fenbendazole, oxfendazole;
3) Halogenated BZD thiols: triclabendazole;
4) *pro-BZD*: thiophanate, febantel, netobimin.

Different modifications at positions 2- and 5- of the BZD ring system (see Figure 39.1) have provided the most anthelmintically active drugs, especially, with the discovery of sulfur-containing methylcarbamate derivatives such as albendazole and fenbendazole, which exhibit high efficacy against lungworms and inhibit larval stages of most GI nematodes. The BZD methylcarbamates are the most used BZD compounds. Albendazole, fenbendazole and their sulfoxide derivatives (albendazole sulfoxide and oxfendazole, respectively) (ruminants), fenbendazole and oxfendazole (horses), febantel, fenbendazole, and mebendazole (companion animals), fenbendazole and flubendazole (poultry and pigs) are currently among the most extensively used BZD methylcarbamate anthelmintics in veterinary medicine.

Pharmacodynamics: Mode of Action

Microtubules are hollow tubular organelles that exist in a dynamic equilibrium with tubulin, the microtubule subunit. Tubulin is a dimeric protein comprised of α- and β-subunits. The BZD and pro-BZD pharmacological activity is based on the binding to parasite β-tubulin, which produces subsequent disruption of the tubulin–microtubule dynamic equilibrium (see Lacey, 1990 for detailed information). Competitive binding experiments using tubulin from mammalian, invertebrate, or fungal cells indicate that BZD compounds bind within the colchicine (a well recognized microtubule inhibitor) binding domain on tubulin. Thus, all the functions ascribed to microtubules at the cellular level are altered (cell division, maintenance of cell shape, cell motility, cell secretion, nutrient absorption, and intracellular transport) (Lacey, 1988). Microtubules are found in animals, plants, and fungi cells. However, the rate constant for the dissociation of BZD from parasite tubulin is much lower than the rate constant for the dissociation from mammalian tubulin. These differences in dissociation rates between BZD and tubulin in host and parasites may explain the selective toxicity of BZD compounds to parasites and its wide safety margin in the mammalian host. The microtubule loss observed at tegumental and intestinal level in cestodes and nematodes after BZD treatment is followed by loss of transport of secretory vesicles and decreased glucose uptake. A prolonged storage of secretory material within the cells is followed by cell disintegration. Cell autolysis requires a period of 15–24 hours posttreatment. Additionally, the inhibition of secretion of nematode acetylcholinesterase and inhibition of some enzymatic activities (such as fumarate reductase, malate dehydrogenase, phosphoenol pyruvate reductase, and succinate dehydrogenase) have been associated with the BZD anthelmintic action. However, all these effects may be related to the primary underlying BZD mechanism: the disruption of the tubulin–microtubules dynamic equilibrium. The effects of structural modifications to BZD-like molecules on microtubule inhibitory activity have been intensively investigated (reviewed by Lacey, 1988). It has been postulated that the presence of a carbamate group in the 2- position is essential for potent microtubule inhibitory activity. Additionally, regardless of the size of the substituent in the 5- position, the pharmacological effect heavvily depends on the nature of the molecule adjacent to the BZD ring system. Different studies suggest that not only the chemical substitution in the position 5- of the BZD ring, but also its conformational arrangement, are relevant in the access of the drug to the active site and in the resultant anthelmintic activity.

Pharmacokinetic Behavior

The anthelmintic activity of BZD compounds not only depend on its binding to β-tubulin, but also on their ability to reach high and sustained concentrations at the site of parasite location, which allow the delivery of effective concentrations of the compound at the receptor within the parasite cells, in sufficient time, to cause the therapeutic effect (Thompson et al., 1993). As a chemical class, the BZD methylcarbamates have only limited water solubility and small differences in drug solubility may have a major influence on their absorption and resultant pharmacokinetic behavior. The lack of water solubility is an important limitation for the formulation of BZD compounds, which mainly allows their preparation as suspensions, pastes, or granules for oral or intraruminal administration. Poor/erratic GI absorption is a common inconvenience for the systemic availability of enterally administered BZD suspensions in most species. The mucous surface in the GI tract behaves as a lipid barrier for the absorption of active substances, so that absorption depends on lipid solubility and degree of ionization at GI pH levels. However, drug particles must dissolve in the enteric fluids to facilitate absorption of the BZD molecule through the GI mucosa. A drug that does not dissolve in the GI contents, passes down and is excreted in the feces without exerting its action. The BZD methylcarbamates show only limited GI absorption due to their poor solubility in water. Their dissolution rate, passage along the GI tract, and absorption into the systemic circulation, are markedly slower than those observed for the more hydrosoluble BZD thiazolyls (TBZ, thiabendazole). Such a phenomenon also results in extended residence times for the active metabolites of the BZD methylcarbamates compared to those of TBZ. This differential pharmacokinetic behavior accounts, in part, for the greater anthelmintic potency of fenbendazole and albendazole compared with thiabendazole.

Pharmacokinetics and Metabolism in Ruminant Species

Absorption

The complexity of the ruminant digestive tract in comparison to that of the monogastric animal creates unique problems and opportunities related to the absorption of drugs administered orally. The rumen may substantially influence the absorption pattern and the resultant pharmacokinetics and antiparasite activity of enterally delivered BZD anthelmintics. The rumen accounts for about 20% of the animal’s volume and never empties. When a BZD suspension is deposited in the rumen, solid particles mix and distribute through the digesta volume.

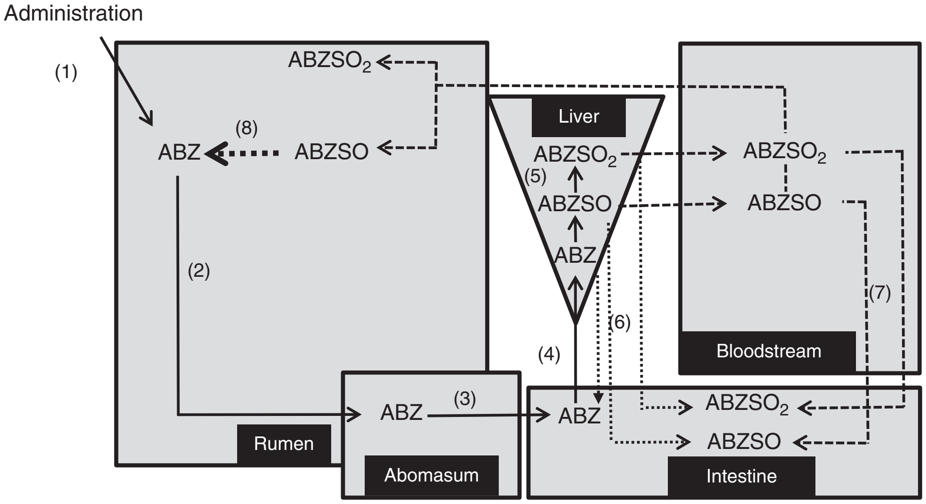

Figure 39.2 Schematic representation of the main pharmacokinetic features taking place after oral/intraruminal administration of benzimidazole anthelmintics in ruminants. See the text for further explanation. Albendazole (ABZ) is used as a model drug in the scheme.
(1) Route of administration: only oral or intraruminal routes can be used for the sulfide compounds (ABZ, FBZ).
(2) Rumen: marked drug dilution. The rumen's reservoir effect is by drug adsorption to particulate digesta.
(3) Abomasum: the acidic pH facilitates drug particles dissolution and strong "ionic trapping" of the drug/metabolite at the abomasum.
(4) Small intestine: main drug absorption site.
(5) Liver: drug oxidative metabolism.
(6) Biliary system: drug excretion (unconjugated and conjugated metabolites), enterohepatic recycling.
(7) Bloodstream: metabolites distribution to different organs/tissues, including active secretion to gastrointestinal tract.
(8) Rumen: sulforeductive biotransformation by ruminal microflora.
ABZ, albendazole parent compound; ABZSO, albendazole sulfoxide; ABZSO$_2$, albendazole sulfone.

Shortly after administration, BZD compounds are almost completely associated (adsorbed) to the digesta particulate material. The drug reaches an equilibrium between the particulate and fluid portions of the digesta. The drug dissolved in the GI fluid is available for absorption and/or for diffusion through the external surface of the helminth parasite located at the GI lumen. The adsorption of BZD particles to digesta solid content, the slow mixing and long digesta residence time, and the large rumen volume assists absorption by delaying the rate of passage of drug down the GI tract (Hennessy, 1993). The rumen acts as a drug reservoir by slowing the digesta transit time throughout the abomasum, which results in improved systemic availability of BZD compounds as a consequence of a greater dissolution of drug particles in the acid pH of the abomasum (Lanusse and Prichard, 1993a). The plasma levels of the parent sulfides (i.e., albendazole, fenbendazole) and/or its active sulfoxide metabolites (albendazole sulfoxide, oxfendazole) reflect the amount of dissolved drug at the GI level (Figure 39.2). Since the main mechanism of drug entry to nematode parasites located in the GI lumen is drug diffusion through its external surface, the higher the concentration of solubilized drug in the GI fluid, the greater the anthelmintic activity. The influence of the rumen on BZD absorption is evidenced by the higher and more sustained concentration of fenbendazole, oxfendazole, albendazole, and their metabolites recovered in the bloodstream after oral/intraruminal treatments compared to intraabomasal administration of the same compounds in sheep (Prichard et al., 1978; Marriner and Bogan, 1981).

A lack of proportionality in the relationship between albendazole dose rates and drug systemic exposure has been described in sheep, where area-under-the-curve (AUC) and maximum peak concentration (C_{max}) values for albendazole sulfoxide increased more than expected from the increase in the dose. The enhanced systemic exposure achieved after albendazole treatments at the highest dose rates correlated with significant increment in drug efficacy against a resistant *Haemonchus contortus* strain (Alvarez et al., 2012).

Metabolism and Elimination

BZD and pro-BZD anthelmintics are extensively metabolized in all mammalian species studied. As a common pattern among different BZD compounds, the parent drug is short lived and metabolic products predominate in plasma and all tissues and excreta of the host, as well as in parasites recovered from BZD-treated animals (Fetterer and Rew, 1984; Alvarez et al., 1999, 2000). The primary metabolites usually are products of oxidative and hydrolytic processes and are all more polar and water soluble than the parent drug. In addition, phase

II conjugative reactions are highly important in the detoxification of BZD-derived products. The oxidized and hydrolyzed metabolites are conjugated with glucuronide and/or sulfate to increase their polarities, which facilitates urinary or biliary excretion. Since BZD anthelmintics are mainly administered by the oral route, "first-pass" metabolism is relevant in the kinetic behavior of these compounds. Intestinal, liver, and lung metabolism have been implicated in this phenomenon in most animal species. Additionally, GI metabolism is an important concern in ruminant species.

Netobimin (pro-BZD) is an anthelmintically inactive nitrophenylguanidine prodrug. Netobimin is nitroreduced and cyclized into albendazole in a microflora-mediated reductive reaction in the GI tract (Lanusse et al., 1993a). The nitro-reduction and cyclization of netobimin into albendazole in the host are crucial for the pharmacokinetic profile of its active metabolites and resultant anthelmintic activity. Both formulation and route of administration may dramatically affect the rate of netobimin conversion and the bioavailability and disposition of its main plasma metabolites, albendazole sulfoxide and albendazole sulfone. Sheep and cattle ruminal and ileal fluids can convert netobimin into albendazole under in vitro conditions (Lanusse et al., 1992b). However, the subcutaneous administration of netobimin resulted in lower plasma concentrations of active metabolites compared to those measured after oral administration of the prodrug in sheep and cattle (Lanusse et al., 1990). In conclusion, oral administration results in an improved pharmacokinetic profile of netobimin metabolites, which accounts for some advantageous anthelmintic efficacy after the oral/intraruminal compared to the parenteral treatment.

Febantel is a phenylguanidine prodrug, which is hydrolyzed by removal of a methoxyacetyl group and then cyclized to fenbendazole. Fenbendazole is then converted to oxfendazole and fenbendazole sulfone in subsequent oxidative metabolic steps. Following febantel administration, in both sheep and cattle, the parent drug is not found in plasma, or is detected in low concentrations for only a short period. In contrast to the extensive GI metabolism described for netobimin, only a low proportion of febantel is bioconverted by sheep and cattle ruminal fluids (Beretta et al., 1987). Hepatic metabolism appears to be the main site of febantel conversion into fenbendazole, after its oral administration to different animal species. The active molecule of the pro-BZD thiophanate is an ethyl BZD carbamate metabolite known as lobendazole (Delatour et al., 1988), formed in the liver with conversion rates of 34% (sheep), 52% (goats), and 57% (cattle). Thiophanate is currently used as an antifungal agent (thiophanate-methyl) for plants.

Hepatic and extrahepatic oxidative metabolism: The metabolism of BZD heavily depends on the substituent present at position 5- of the BZD ring system and involves a variety of reactions. Phase I reactions have been observed at position 5-. Hydroxylations of thiabendazole, albendazole, and fenbendazole have been demonstrated in different animal species. The sulfoxidation of albendazole and fenbendazole at the sulfur atom of the substituent group at the carbon 5- of the BZD nucleus have been widely investigated. The oxidations of albendazole to albendazole sulfoxide and fenbendazole to oxfendazole have been shown to be catalyzed by the liver microsomal mixed function oxidases in different species (Galtier et al., 1986a; Souhaili El Amri et al., 1987; Montesissa et al., 1989; Lanusse et al., 1993b; Virkel et al., 2004). Additionally, the anthelmintically active sulfoxide derivatives undergo a second, slower and irreversible oxidative step, forming the inactive sulfone (albendazole sulfone and fenbendazole sulfone) metabolites, which are also found in the bloodstream and tissues after administration of their respective parent sulfides.

The substitution of the BZD ring in position 5- has been particularly important in determining the metabolic fate of BZD methylcarbamates. This position is metabolically labile and has permitted retardation of the biotransformation of 5-substituted BZD anthelmintics as well as improvement of their efficacy (Hennessy et al., 1989). The nature of this substitution at position 5- markedly influences the sequence of BZD liver metabolism. Aromatic BZD derivatives, such as fenbendazole and oxfendazole, require more extensive hepatic oxidative metabolism than aliphatic derivatives (albendazole and albendazole sulfoxide) to achieve sufficient polarity for excretion (Hennessy, 1993). Consequently, the rates of albendazole liver microsomal sulfoxidation in sheep and cattle were higher than those observed for fenbendazole (Virkel et al., 2004). For this reason, low fenbendazole concentrations are recovered in plasma following its oral/intraruminal administration to sheep and cattle, whilst albendazole is not detected in the bloodstream after its administration as the parent drug in both species. Moreover, longer plasma mean residence times and elimination half-lives for fenbendazole and its metabolites, compared to those of albendazole metabolites, were observed in sheep and cattle (Lanusse et al., 1995) (Figure 39.3).

The involvement of the cytochrome P450 (CYP) and flavin monooxygenase (FMO) systems on the liver sulfoxidation of albendazole has been demonstrated in different animal species, including sheep (Galtier et al., 1986a) and cattle (Lanusse et al., 1993b). It has been demonstrated that FMO-mediated sulfoxidation accounted for up to 60% of albendazole sulfoxide production from albendazole, whilst CYP contributed 40% in both sheep

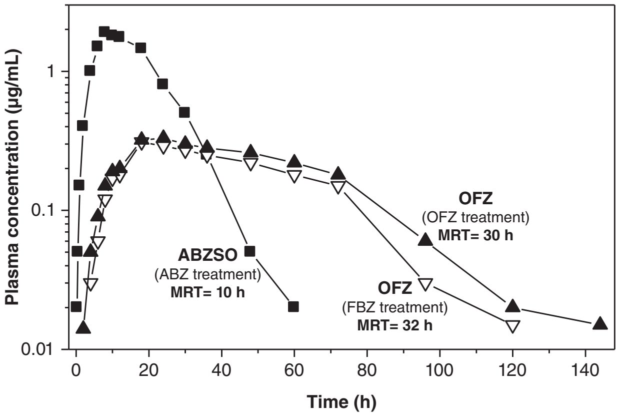

Figure 39.3 Comparative mean (n = 5) plasma concentrations of the benzimidazole sulfoxide metabolites, albendazole sulfoxide (ABZSO) and oxfendazole (OFZ), obtained after oral administration of albendazole (ABZ), fenbendazole (FBZ), and OFZ (5 mg/kg) to adult sheep (see the text for further explanation). and cattle liver microsomes (Virkel et al., 2004) (Figure 39.4). Similarly, FMO was estimated to be the main enzymatic system involved in the liver sulfoxidation of fenbendazole (~80%) in both species (Virkel et al., 2004). Inhibition of CYP-mediated sulfoxidation by piperonyl butoxide demonstrated the participation of this enzymatic system in the hepatic metabolism of fenbendazole in horses (McKellar et al., 2002).

Both sulfoxide metabolites (albendazole sulfoxide and oxfendazole) have an asymmetric center in the sulfur atom of their side chains. This nucleophilic sulfur atom is attached to four different functional groups, which results in an asymmetric molecule nonsuperimposable with its mirror image. Thus, two different enantiomers of albendazole sulfoxide and oxfendazole have been identified (by chiral separation) in the plasma of sheep and cattle treated with albendazole and fenbendazole (prochiral molecules), respectively (Delatour et al., 1990a; Sánchez et al., 2002). It has been shown that (+)albendazole sulfoxide is the main enantiomeric form recovered in plasma and tissues at parasites locations (Alvarez et al., 2000) following albendazole treatment of sheep (Figure 39.5) and cattle. The same pattern was observed after albendazole sulfoxide administration to cattle (Cristofol et al., 2001). Most importantly, the (+)albendazole sulfoxide enantiomer seems to have a higher anthelmintic activity than that observed for the (−) enantiomer (Paredes et al., 2013). Similarly, (+)oxfendazole prevails in the systemic circulation after both fenbendazole and oxfendazole administrations to sheep (Delatour et al., 1990a; Sánchez et al., 2002) and cattle. The observed differences in the plasma/tissues availabilities of the (+) and (−) enantiomeric forms were attributed to the relative contribution of the FMO and CYP-dependent oxygenases to albendazole and fenbendazole hepatic sulfoxidation. FMO and CYP are known to be oppositely enantioselective (Cashman, 1998). FMO activity accounted for 94% (cattle) and 81% (sheep) of (+)albendazole sulfoxide production in liver microsomes (Virkel et al., 2004). In both species, the enantioselectivity of the hepatic FMO system towards (+)albendazole sulfoxide production was close to 100%. Moreover, it has been shown that (−)albendazole sulfoxide, rather than its (+) antipode, is the main substrate for the CYP-mediated formation of the inactive sulfone metabolite (Delatour et al., 1991; Benoit et al., 1992). On the other hand, FMO-mediated sulfoxidation of fenbendazole generated

Figure 39.5 Schematic representation of the ruminal biotransformation of albendazole sulfoxide (ABZSO) enantiomers. The width of the arrows indicates the magnitude of the metabolic reactions. The main pharmacological features of the (+) sulfoxide enantiomer (compared to the (–) isoform) are listed in the bottom box. The enantioselective ruminal sulforeduction of the (+) isoform is the most relevant metabolic reaction for the formation of the parent thioether (ABZ). The same pattern is applicable to the sulforeduction of oxfendazole (OFZ) enantiomers into fenbendazole (FBZ) (see the text for detailed explanation). Source: Adapted from Virkel et al., 2004. Reproduced with permission of the American Society for Pharmacology and Experimental Therapeutics.

both (+) and (–)oxfendazole enantiomers. Fenbendazole oxidation was enantioselective towards the production of (+)oxfendazole in both sheep (65%) and cattle (79%). In conclusion, the sulfoxide metabolite recovered in plasma and target tissues after either albendazole or fenbendazole administration exists as two different chemical entities: the (+) and (–) enantiomeric forms (Figure 39.4).

Biotransformation takes place predominantly in the liver, although metabolic activity is apparent in extrahepatic tissues such as lung parenchyma and small intestine mucosa. Large quantities of albendazole parent drug were recovered from tissues at parasite locations in both sheep and cattle. Similarly, fenbendazole has been recovered from tissues at parasite locations following oral administration of oxfendazole to cattle. Altogether, these findings support the need to study the biotransformation of BZD anthelmintics in extrahepatic tissues such as lung parenchyma and small intestinal mucosa. The sulfoxidation of albendazole and fenbendazole by small intestine (cattle) and lung (sheep and cattle) microsomes was shown to be enantioselective (Virkel et al., 2004). Although the liver is the main site of albendazole and fenbendazole biotransformation, sulfoxidation in the intestinal mucosa and lung tissue may contribute to the presystemic metabolism of both anthelmintic drugs and should not be underestimated.

The administration of thiabendazole results in a rapid conversion of a parent compound into a 5-hidroxy thiabendazole metabolite, formed by aromatic ring hydroxylation. Although this metabolite is sufficiently polar for a rapid urinary excretion, both its unconjugated and sulfate or glucuronide conjugated forms have been found in urine of TBZ treated animals (Tocco et al., 1965; Gottschall et al., 1990).

After the administration of mebendazole to sheep, the parent drug is rapidly absorbed and metabolized into two main metabolites, which are identified in sheep plasma after mebendazole treatment (Behm et al., 1983). The main mebendazole metabolite results from carbonyl reduction to the secondary alcohol, which was also identified as its glucuronide or sulfate conjugates. Although, the specific enzymatic system responsible for mebendazole reduction is unknown, several cytosolic ketone reductases are involved in the formation of hydrosoluble metabolites from carbonyl-containing molecules. On the other hand, the combination of carbonyl reduction and carbamate hydrolysis produces the hydrolyzed metabolite of mebendazole. Hydrolysis of the carbamate group eliminates both the anthelmintic activity of the compound and its toxicity. Mebendazole rather than its metabolites appears to be the active anthelmintic molecule. Mebendazole metabolites are mainly excreted in bile.

Unlike aromatic substituted methylcarbamates, 5-aliphatic substituted such as albendazole and parbendazole, when oxidized, are sufficiently polar to be largely excreted in urine rather than undergo further conjugation and secretion in bile (Hennessy et al., 1989). For instance, following albendazole treatment to sheep only 8% of the total dose was recovered in bile as unconjugated albendazole sulfoxide and hydroxyalbendazole sulfoxide metabolites, and 6.3% as conjugated glucuronide and sulfate esters, mainly of 2hydroxy-albendazole sulfoxide and 2hydroxy-albendazole sulfone (Hennessy et al., 1989); 59% of the dose was recovered in urine of albendazole-treated cattle (Gyurik et al., 1981). On the other hand, the percentage of a fenbendazole dose in cattle recovered in urine (2.5%) was markedly lower than that recovered from feces (42%), the latter being mainly the unchanged fenbendazole parent compound (Short et al., 1987).

The parent flubendazole compound and its reduced and hydrolyzed metabolites have been identified in tissues of treated pigs, poultry, and sheep. After flubendazole intravenous administration to sheep, the parent drug was rapidly depleted from the bloodstream (Moreno et al., 2004), being detectable up to 36 hours post-treatment. The reduced metabolites (main metabolite) and hydrolyzed metabolites were rapidly detected in the bloodstream, which indicated a fast biotransformation of flubendazole to form both metabolic products. In vitro incubations with sheep liver microsomes indicated that flubendazole is converted to reduced flubendazole by the mixed-function oxidase system (Moreno et al., 2004).

Reductive Metabolism in the Gastrointestinal Tract

In comparison to the liver, where oxidative metabolism predominates, the GI microflora is very active in reductive reactions of foreign compounds, particularly those containing -nitro and -sulfoxide groups (Renwick et al., 1986; Rowland, 1986). Drug GI metabolism may be modified by the type of diet and many other factors affecting the GI bacterial reductive capacity. Orally administered compounds that are poorly absorbed from the GI tract will stand the greatest chance of undergoing metabolism by the microflora, although a large number of drug/metabolites gain entry to the gut via biliary secretion or plasma–GI distribution exchange (Figure 39.2) and will also be exposed to microbial activity. Drug metabolic processes taking place in the rumen are particularly important in ruminant therapeutics.

The metabolic sulforeduction of the BZD sulfoxide metabolites (albendazole sulfoxide and oxfendazole) to form the parent thioethers (albendazole and fenbendazole, respectively) has been shown to occur in ruminal and intestinal fluid contents from sheep and cattle (Lanusse et al., 1992b). A plasma–GI pH gradient (Lanusse et al., 1993a) and/or an active gastric secretion process (Alí and Hennessy, 1995) account for the distribution of BZD metabolites from plasma to the digestive tract lumen. Therefore, albendazole sulfoxide and oxfendazole can be reduced back to their respective thioethers by ruminal and intestinal microflora and may act as a source of albendazole and fenbendazole, respectively, in the GI tract. This GI metabolic reduction may be of primary importance for the antiparasitic efficacy of BZD thioethers. Since the thioethers have a greater affinity for parasite tubulin than the sulfoxides (Lacey, 1990; Lubega and Prichard, 1991), this bacteria-mediated reduction may have significant importance for the efficacy against GI parasites. Thus, the high efficacy of albendazole sulfoxide and oxfendazole against GI parasites may depend on this bacterial reduction of the sulfoxide to the more pharmacologically active thioethers.

The ruminal sulforeduction of both albendazole sulfoxide and oxfendazole is enantioselective, the (+) antipode being the main substrate to form the more active parent sulfide in the rumen (Virkel et al., 2002) (Figure 39.5). Chiral inversion is the metabolic process by which one enantiomer is transformed into its antipode. The chiral inversions of (+) into (−), but also from (−) into (+) enantiomeric forms, were observed when both enantiomers were incubated separately (as pure substrates) with ruminal fluid obtained from both sheep and cattle (Virkel et al., 2002) (Figure 39.5). Thus, the reported data suggest that chiral inversion of albendazole sulfoxide and oxfendazole enantiomers is likely to be bidirectional and may depend on either the metabolic transformation of one enantiomer into its antipode or through the formation of parent thioether (albendazole or fenbendazole) as an intermediate metabolic product. Overall, the work published by Virkel et al. (2002) demonstrates that the ruminal sulforeduction of both albendazole sulfoxide and oxfendazole is enantioselective, the (+) antipode being the main substrate to form the more active parent sulfide in the rumen.

Distribution to Parasite Location Tissues

Release from the dosage form and absorption precede entry of any anthelmintic molecule into the bloodstream, which serves as the tissue in which drug and metabolite molecules are conducted to various parts of the body. Within the bloodstream, a fraction of most drugs binds reversibly to plasma proteins, and the remainder undergoes simultaneous distribution, metabolism, and excretion. The access of BZD molecules to intracellular sites depends upon their ability to penetrate the capillary endothelium and to cross the cell membrane. Most anthelmintics are weak organic acids or bases and exist in solution, at physiological pH, as both nonionized and ionized forms; while the poor lipophilicity of the ionized molecules excludes them from passive diffusion, the lipid-soluble nonionized moieties passively diffuse across biological membranes until equilibrium is established. Once the BZD molecule has been absorbed from the GI tract, it is rapidly distributed by the circulatory system throughout the entire body. During this time, the metabolic processes necessary to facilitate its elimination commence. Extensive tissue distribution of albendazole and its metabolites in sheep (Alvarez et al., 1999) and cattle (Sánchez et al., 1997) have been reported. However, differential distribution patterns among BZD sulfides (albendazole, fenbendazole), sulfoxide (albendazole sulfoxide, oxfendazole), and sulfone (albendazole sulfone, fenbendazole sulfone) metabolites, based on their differential lipophilicities, may be expected. The distribution rate, which is indicated by the apparent volume of distribution, depends on molecular weight, lipid solubility, and plasma protein binding of each drug/metabolite. The majority of BZD compounds show a binding of less than 50% to plasma protein, relatively high volume of distribution, and a relatively fast elimination rate in ruminant species.

The rate of absorption, metabolism, and excretion of BZD anthelmintics varies from drug to drug, with slower absorption and prolonged recycling between enteral and parenteral tissues being relevant to enhance efficacy. Worms attached to the lining of the gut may be more exposed to this recycling drug than to that actually passing down the GI tract in food that is being digested. Fenbendazole, oxfendazole, and albendazole are less water soluble than earlier members of the group and, therefore, their dissolution rate, passage along the GI tract, and absorption into the systemic circulation are markedly slower compared to thiabendazole. These more lipophilic substituted BZD methylcarbamate compounds remain in the bloodstream for a longer time and, since it is assumed that an equilibrium exists between plasma and GI tract, the period of exposure of GI nematodes to effective drug/metabolites concentrations is extended. In NTB-treated cattle, peak concentrations of albendazole sulfoxide and albendazole sulfone are reached at 7–10 hours (albendazole sulfoxide) and at 15–22 hours (albendazole sulfone) posttreatment, followed by a well-defined decline in concentration in both plasma and GI compartments. However, whereas plasma concentration fell to undetectable levels (30–36 hours posttreatment), the profile of these metabolites in the rumen, abomasum, and ileum showed an "extra" slow elimination phase that extended to 72 hours posttreatment (Figure 39.6). This pharmacokinetic behavior is particularly clear for the albendazole sulfoxide and sulfone metabolites, whose elimination half-lives in both the abomasum and ileum were significantly longer compared to plasma. This metabolite-distribution process, also described for fenbendazole metabolites in cattle, may be driven by a plasma/GI tract pH gradient. The ratio of nonionized to ionized forms depends upon the pKa of the drug and the pH of the fluid in which the drug is dissolved, and the pH gradient between plasma and different tissues dictates the concentrations of drug/metabolite at either side of the separating cell membranes; at equilibrium, there will be a higher total concentration of the drug on the side of the membrane where the degree of ionization is greater. For instance, albendazole sulfoxide is an amphoteric compound which can act as either acid or base. Its pKa values are 3.45 and 9.8 for the acidic and basic groups, respectively. At plasma pH, there will be an important proportion of this molecule under the nonionic form, which will facilitate its passive diffusion from plasma to parasite location tissues. A greater plasma/abomasum pH gradient compared with that of the rumen and ileum would produce a strong ionic trapping effect (Figure 39.6), which would account for the significantly higher concentrations of albendazole metabolites found in the abomasum in comparison with plasma and other GI compartments. In addition, although albendazole (the most potent anthelmintic molecule) is not detected in the bloodstream, it has been recovered in different GI compartments, with particularly high concentration profiles recovered in the abomasal mucosa as well as from *Haemonchus contortus* recovered from treated sheep (Figure 39.7). The extensive distribution of BZD methylcarbamates from the bloodstream to the GI tract and other tissues may contribute to anthelmintic efficacy against parasites localized in body tissues including GI mucosa, GI lumen, and lungs (Alvarez et al., 1999, 2000). The recovery of both albendazole and fenbendazole parent compounds from GI mucosa and lung tissue after intravenous administration of their sulfoxide derivatives to cattle (as described in Section Reductive Metabolism in the Gastrointestinal Tract), is further evidence of the complex relationship among drug distribution, metabolism, and efficacy of BZD anthelmintics in ruminants.

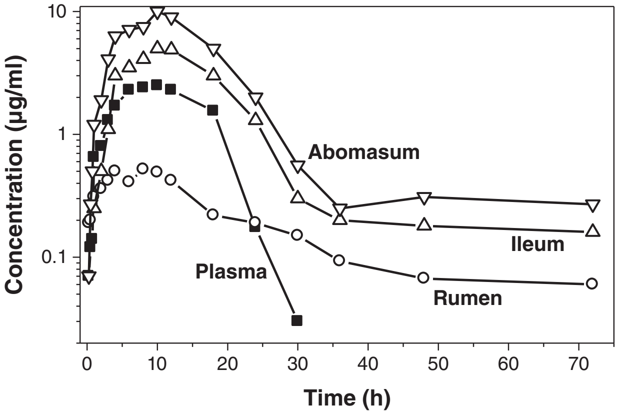

Figure 39.6 Comparative albendazole sulfoxide (ABZSO) concentration profiles measured in the bloodstream and in different gastrointestinal compartments after the oral administration of netobimin prodrug (20 mg/kg) to cattle. The results shown the slow elimination phase observed in digestive compartments (compared to plasma), which is critical for efficacy against gastrointestinal nematodes (see the text for further explanation). ABZSO elimination half-life values were: 2.29 hours (plasma), 16 hours (rumen), 34 hours (abomasum), and 67 hours (ileum). Source: Adapted from Lanusse et al., 1993a. Reproduced with permission of John Wiley & Sons.

Comparative studies have revealed considerable differences between ruminant species regarding the pharmacokinetics of anthelmintic drugs. Longer residence times for albendazole sulfoxide in sheep than in cattle, and higher plasma AUC ratios for albendazole sulfone/albendazole sulfoxide in cattle, have been consistently reported. Since sheep liver microsomes has a higher albendazole sulfoxidase activity compared with that of cattle, the greater capacity of sheep GI fluids to reduce albendazole sulfoxide back to albendazole may explain the observed species-related pharmacokinetic differences. On the other hand, the oxfendazole AUC after oxfendazole administration to goats was 39% smaller compared to that observed in sheep (Hennessy et al., 1993a). It is suggested that goats possess a faster hepatic metabolism than sheep, resulting in more rapid elimination of oxfendazole. This lower availability may account for the poor efficacy reported for oxfendazole

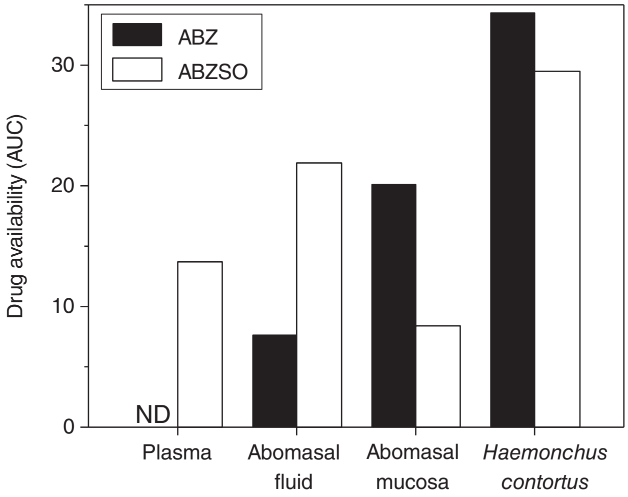

Figure 39.7 Comparative albendazole (ABZ) and albendazole sulfoxide (ABZSO) availabilities (expressed as area under the concentration vs. time curve, AUC), obtained in plasma, abomasal fluid, abomasal mucosa, and *Hemonchus contortus* recovered from infected sheep treated with ABZ (intraruminal at 7.5 mg/kg) (see the text for further explanation). ND, not detected. AUC values are expressed in μg.h/g. Source: Data from Alvarez et al., 2000.

- *ABZSO was the main active molecule measured in plasma after ABZ treatment in sheep*
- *High concentrations of ABZ and ABZSO were recovered from H. contortus*
- *ABZ total availability was greater in H. contortus compared to abomasal tissue/fluid*

given to goats at the dose recommended for sheep. These observations suggest that extrapolated data can be misleading in predicting adequate dosages and withdrawal times.

Pharmacokinetics in nonruminant species

The oral administration of BZD (fenbendazole, oxfendazole) compounds in horses demonstrated that reduced bioavailability and shorter residence times are obtained in comparison to those observed in ruminants. Following oral administration of either fenbendazole or oxfendazole (10 mg/kg) to horses, the inactive fenbendazole sulfone metabolite is the predominant analyte measured in plasma, with AUC ratios oxfendazole/fenbendazole/fenbendazole sulfone of approximately 3/1/9 (oxfendazole treatment) and 1/4/7 (fenbendazole treatment) (McKellar et al., 2002). In both cases, the time to reach the peak plasma concentration of the active oxfendazole metabolite was approximately 9 hours, which is earlier compared to that observed in ruminants (21–29 hours) and agrees with the reduced systemic availability observed in horses. Following oxibendazole oral administration to horses (10 mg/kg), parent oxibendazole could only be detected in plasma up to 1 hour posttreatment; an unidentified metabolite was recovered in the bloodstream between 0.5 and 72 hours (Gokbulut et al., 2002). Oxibendazole in vitro conversion into its metabolite was significantly inhibited by coincubation with the cytochrome P450 inhibitor piperonyl butoxide. These findings indicate that a first-pass metabolism may reduce oxibendazole systemic availability in horses.

As described for ruminant species, albendazole is not detected in plasma after its oral administration to pigs (Alvarez et al., 1995). Albendazole sulfoxide and albendazole sulfone are the main metabolites recovered from plasma up to 48 hours posttreatment. The pattern of plasma metabolites is similar to that reported after the administration to ruminant species and there appear to be no major differences between the metabolic patterns of albendazole observed in pigs and sheep. However, marked differences in the metabolism of albendazole between cattle and pigs have been described, with predominance of the sulfoxide metabolite over albendazole sulfone in pig plasma, while the inverse is observed in cattle after albendazole treatment. Similar to the observations in ruminants, the time of residence of the albendazole suspension at the acidic pH of the stomach in the pig affects its dissolution rate and the subsequent absorption of the drug from the gut. Any factor that influences gastric emptying rate may have a profound effect on the rate and extent of BZD absorption in monogastric animals. After oral fenbendazole administration to pigs, oxfendazole (the main metabolite recovered) and fenbendazole sulfone are rapidly detected in plasma up to 48 hours posttreatment. Oxfendazole reaches a C_{max} value (0.7 μg/ml) at 12.5 hours posttreatment (Petersen and Friis, 2000). The bioavailability of fenbendazole in pigs after its oral administration was estimated to be about 30%. This low value is a consequence of the low water solubility of fenbendazole and its poor GI absorption, plus the significant liver first-pass effect on the drug. Interestingly, fenbendazole was measured in the bloodstream of oxfendazole-treated pigs. Its presence could be explained by oxfendazole reduction, which probably takes place in the pig large intestine, where an important microbial activity is present, as it is the main site of cellulose degradation in this species.

The gut transit time influences the dissolution and absorption of poorly water-soluble drugs such as the BZD anthelmintics. The drugs that do not dissolve in GI contents pass down and are excreted in the feces without exerting their action. The GI physiology and the digesta transit time are markedly different between monogastric species and ruminants. This is relevant for dogs and cats, whose GI transit times are significantly shorter compared to ruminant species; this has a marked effect on the absorption, kinetic behavior, and efficacy of BZD anthelmintics in companion animals. Albendazole, albendazole sulfoxide, fenbendazole, febantel, or mebendazole, formulated as tablets or suspensions for oral administration in dogs and cats, must dissolve at low pH (stomach), and it has been demonstrated that the dissolution rate may be altered according the size of the formulation particle (Hennessy, 1993). Several studies suggest that only limited rates of dissolution and absorption of BZD anthelmintics are achieved in the cat, dog, and man. Consequently, these compounds may need to be given at a higher dose or as multiple administrations in order to maintain therapeutic concentrations and, therefore, to achieve acceptable anthelmintic efficacy (Roberson and Burke, 1982; Edwards and Breckenridge, 1988).

Mebendazole is poorly absorbed after oral administration and only low concentrations (representing 10% or less of the total administered dose) of mebendazole parent drug and its inactive metabolite, hydroxymebendazole, were recovered in plasma of humans and dogs after oral treatment (Witassek et al., 1981; Edwards and Breckenridge, 1988). This observation could explain the lack of efficacy of mebendazole against lung parasites in humans and dogs and the need for multiple dose treatments. The pharmacokinetics of fenbendazole parent drug and its metabolites in dogs has been characterized (McKellar et al., 1990). Fenbendazole parent drug, its active sulfoxide (oxfendazole), and inactive sulfone (fenbendazole sulfone) metabolites were recovered in plasma for 48 hours after administration of a single oral dose of 20 mg/kg. Interestingly, plasma concentrations for both active molecules (fenbendazole and oxfendazole) are depleted in parallel from the body, giving an AUC ratio (fenbendazole : oxfendazole) of approximately 0.82. This may result in exposure of target parasites to the fenbendazole moiety (which has greater potency than oxfendazole), accounting for some advantageous activity against the tissue-arrested larvae and other immature parasite stages (McKellar et al., 1990). When albendazole was given as a single dose in tablet form, albendazole sulfoxide and albendazole sulfone were the main metabolites detected in plasma for up to 16 hours posttreatment (Sánchez et al., 2000a). Compared to ruminants, where the rumen acts as drug reservoir, effective treatment in monogastrics requires more prolonged, multidose regimes of at least 3 to 5 days, depending on the dose used. There are conclusive pharmacokinetic results to support the concept that higher efficacy could be expected in dogs and cats by increasing the number of treatments rather than increasing the dose. In fact, the AUC of fenbendazole in dogs was similar after a single administration of fenbendazole at different dose levels over a range between 2.5 and 100 mg/kg (McKellar et al., 1993). Lower fenbendazole plasma concentrations were achieved in dogs when fenbendazole was given on an empty stomach, compared with its administration given in food. However, fat content in the diet does not affect the absorption of fenbendazole after its oral administration to dogs (McKellar et al., 1993).

After the oral administration of fenbendazole to chickens, the parent drug, oxfendazole and fenbendazole sulfone, were detected in plasma, fenbendazole sulfone being the main metabolite recovered up to 96 hours posttreatment (Taylor et al., 1993).

A new formulation albendazole sulfoxide–base (ricobendazole) has been marketed for use in dogs in Latin America. Interestingly, this formulation showed around 500% increase in AUC and C_{max} values when compared to the conventional albendazole tablet formulation (Dib et al., 2011). This increased systemic exposure correlated with enhanced efficacy against most GI helminth parasites, from which this formulation is recommend as a single dose treatments. The improved efficacy obtained at a single (20 mg/kg) dose may be based on the high solubility of albendazole sulfoxide at the different digestive tract pHs compared to albendazole parent drug.

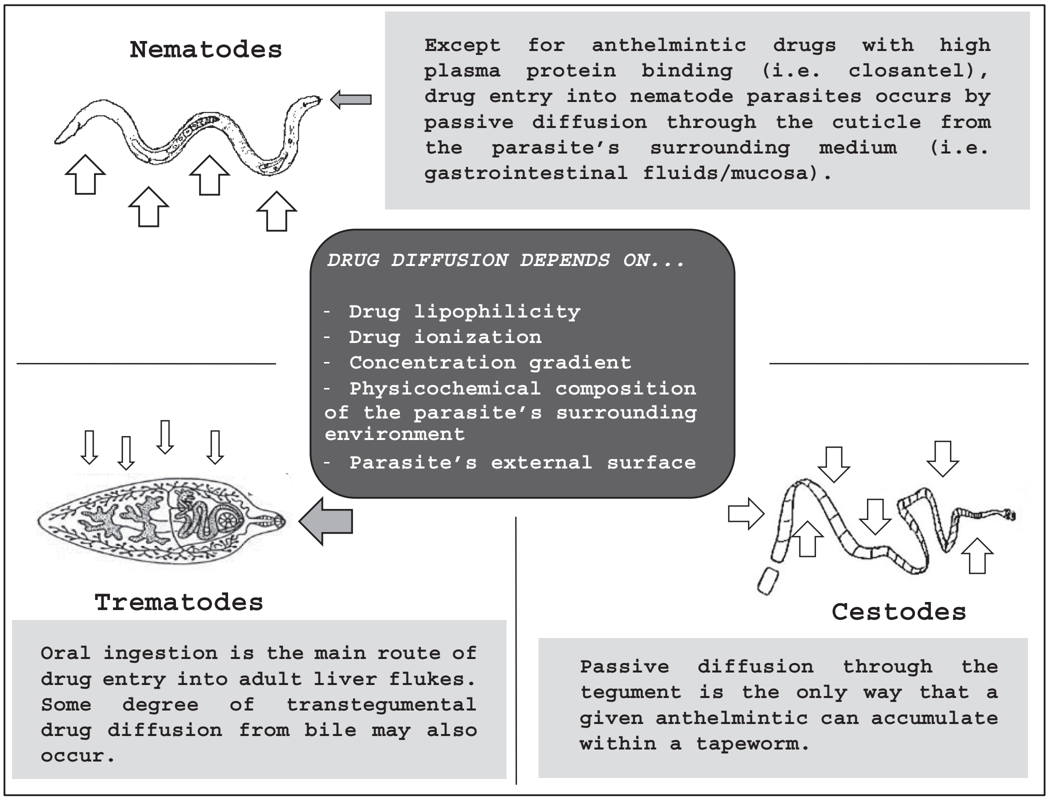
Albendazole parent drug is absorbed slowly and detected between 1 and 6 hours posttreatment in chickens, albendazole sulfoxide being the main metabolite detected, with a peak concentration of 0.83 μg/ml obtained at 1 hour posttreatment (Csiko et al., 1996) and low albendazole sulfone concentrations measured between 2.5 and 30 hours after albendazole administration. Interestingly, while in other animal species, such as pigs, dogs, and ruminants, albendazole is not detected in plasma after its oral administration, the parent drug was measured in hens. This finding has been associated with a fast absorption process and/or a slow metabolic rate in hens compared with other species (Bistoletti et al., 2013). Additionally, while drug absorbed at either proventriculus, gizzard, or intestines reaches the liver drained by the venous portal system, albendazole absorbed at the crop reaches the systemic circulation through the jugular vein, avoiding the liver "first-pass" effect. Data provided for chickens indicated that albendazole and fenbendazole are metabolized in avian species via the same metabolic pathway as in mammals (McKellar and Scott, 1990). As can be expected for dogs, cats, and man, the GI reductive metabolism of the BZD sulfoxide into the parent sulfides is markedly less relevant in poultry compared to ruminant species. Flubendazole is widely used as an anthelmintic in poultry and its main metabolites, hydrolyzed flubendazole and reduced flubendazole, have been identified in tissues of flubendazole-medicated turkeys.

Mechanisms of Drug Transfer into Target Parasites

Understanding the role of the cuticular/tegumental structure on the process of drug uptake by helminth parasites is an area of major scientific interest. It has been shown from in vivo and ex vivo studies that transcuticular diffusion is the predominant pathway for the entry of anthelmintic drugs into nematodes (Cross et al., 1998; Alvarez et al., 2001). Although, there are relevant structural differences between the external surface of nematodes (cuticle) and cestodes/trematodes (tegument), the mechanism of drug entry to both types of helminths seems to be equally dependent on lipophilicity, as a major physicochemical determinant of drug capability to reach therapeutic concentrations within the target parasite. A high correlation between the octanol–water partition coefficients for different BZD anthelmintics and their capacity to diffuse through the tegument of *Moniezia expansa* has been shown (Mottier et al., 2003). The most lipophilic BZD compounds (fenbendazole, albendazole, mebendazole) (partition coefficients >3.7) were measured at higher concentrations within the tapeworm compared to those with the lowest lipid–water partition values (oxfendazole, albendazole sulfoxide, thiabendazole, etc.). A lower diffusion of albendazole and albendazole sulfoxide into *Ascaris suum* compared to *Moniezia* spp. and *Fasciola hepatica* has been demonstrated (Alvarez et al., 2001). Nematodes maintain a strongly buffered environment in the aqueous spaces of the cuticle structure, with a pH value of this compartment around 5.0 (accumulation of organic acids as products of carbohydrate metabolism). The lipid-containing region of the cuticle represents the rate-determining barrier for passive transport: the molecular size, restriction by pores, the intrinsic lipid–water partition coefficient, and pH/pKa relationship are among the rate-determining factors (Ho et al., 1992). BZD molecules largely exist in their ionized form at the acidic environment of the nematode surface, which may limit their diffusion across the cuticle. This ionization-mediated impairment of drug diffusion and the complex structure of the nematode cuticle compared to the cestode/trematode tegument, may explain the drug penetration differences observed between nematode and other helminths (Alvarez et al., 2001). In fact, this work demonstrated that the diffusion of BZD molecules into *Fasciola hepatica* and *Moniezia* spp. is markedly greater than that observed in the nematode *Ascaris suum* maintained under the same ex vivo conditions (Figure 39.8).

The identification of the capability of different helminth parasites to biotransform anthelmintic drugs is considered as another crucial step in the overall interpretation of the pharmacological activity of these drugs. It has been shown that both cytosolic and microsomal fractions obtained from different helminths are able to oxidized albendazole into its sulfoxide derivative. While this oxidative pathway is predominant in *Fasciola hepatica*, the sulforeduction of albendazole sulfoxide into its parent sulfide compound is the main metabolic activity identified in tapeworms (Solana et al., 2001). Additionally, the ex vivo biotransformation of albendazole to different albendazole glucoside metabolites was significantly higher in albendazole-resistant adult *Haemonchus contortus* compared to susceptible worms (Vokřál et al., 2013). The altered activities of certain detoxifying enzymes might partly protect the worms against the toxic effect of the drugs, contributing to a drug resistance mechanism. Although further investigation is required to establish the pharmacological relevance of drug biotransformation in target parasites, particularly regarding its potential impact on the development of resistance, these findings are complementary to studies addressing the understand of mechanisms of drug accumulation in helminths.

Higher albendazole sulfoxide and oxfendazole compared to albendazole and fenbendazole concentrations have been reported in GI fluids of different ruminant species. However, the high lipophilicity of the parent thioethers (albendazole, fenbendazole) assures their penetration through the external surface of parasites. In fact, higher concentrations of albendazole were measured in *Haemonchus contortus* recovered from infected treated sheep compared to those of its sulfoxide metabolite (albendazole sulfoxide) (Alvarez et al., 2000). Since albendazole was not recovered in peripheral plasma, only drug from the pool found in abomasal fluid and mucosal tissue was available to reach the target nematode through its external cuticle. It is also likely that *Haemonchus contortus* may feed on portal blood. However, the low albendazole concentrations recovered in portal blood would not explain the large amount of albendazole recovered from this abomasal parasite. These findings may confirm the relevance of the transcuticular diffusion process, even in a blood-sucking parasite such as *Haemonchus contortus*. The higher anthelmintic potency of albendazole and fenbendazole and their greater capability to diffuse into the parasite, suggest that the parent drug may be the main molecule responsible for the activity against GI parasites. However, a complementary effect of the sulfoxide metabolites may contribute to the overall anthelmintic activity of these BZD compounds. On the other hand,



Except for anthelmintic drugs with high plasma protein binding (i.e. closantel), drug entry into nematode parasites occurs by passive diffusion through the cuticle from the parasite's surrounding medium (i.e. gastrointestinal fluids/mucosa).

DRUG DIFFUSION DEPENDS ON...

- Drug lipophilicity
- Drug ionization
- Concentration gradient
- Physicochemical composition of the parasite's surrounding environment
- Parasite's external surface

Oral ingestion is the main route of drug entry into adult liver flukes. Some degree of transtegumental drug diffusion from bile may also occur.

Passive diffusion through the tegument is the only way that a given anthelmintic can accumulate within a tapeworm.

Figure 39.8 Main routes of in vivo drug entry into different target helminth parasites.

transcuticular transfer appeared to be the main route of passage of other anthelmintic compounds, such as ivermectin, into the filarial nematode *Onchocerca ochengi* (Cross et al., 1998) and *Haemonchus contortus* (Lloberas et al., 2012).

Drug concentration at the site of parasite location and the lipid solubility of the anthelmintic molecule are not the only parameters to consider when drug kinetics are evaluated. The physicochemical characteristics of the tissues and fluids surrounding the parasite may play a relevant role in drug accumulation. The partitioning of the active drug/metabolites between an aqueous gastrointestinal fluid and the lipoidal tissue of the parasite may facilitate the accumulation of the drug within the parasite. This drug partitioning phenomenon may be different for other sites of parasite location such as the biliary tract, where the bile-induced micelle formation may affect the diffusion of the active drug/metabolite into the target parasite (i.e., *Fasciola hepatica*). The physicochemical features of the environment where the target parasite is immersed play a pivotal role in the process of drug access, indicating that some helminths may be protected from the deleterious effect of an anthelmintic drug when living in their predilective location. This phenomenon may also explain many therapeutic failures observed in parasite control in both human and veterinary medicine, which in some cases have contributed to exposure of target parasites to subtherapeutic drug concentrations.

Anthelmintic Spectrum

BZD and pro-BZD were introduced into the animal health market primarily for the control of GI nematodes, not only for use in livestock animals (cattle, sheep, goats, swine, and poultry), but also for horses, dogs, and cats. The use of BZD and pro-BZD compounds quickly became widespread because they offered major advantages over previous available drugs in terms of spectrum, efficacy against immature stages and safety for the host animal. Additionally, BZD anthelmintics have ovicidal activity. With the exception of the halogenated BZD thiol, triclabendazole, which has only flukicidal activity against all stages of *Fasciola hepatica* (see Chapter 40), all BZD and pro-BZD can be classified as broad-spectrum anthelmintics. However, the substituted sulfur-containing methylcarbamates (albendazole, fenbendazole, etc.) and pro-BZDs (febantel, netobimin) have an extended spectrum of activity compared to the earlier BZD thiazolyls (i.e., thiabendazole). It has been demonstrated that the greater potency and spectrum of activity of the newer BZD is largely a function of their pharmacokinetic behavior rather than entirely due to their intrinsic differences in activity. Overall, the BZD methylcarbamate are broad-spectrum anthelmintics active against a variety of GI and lung nematodes, tapeworms, and trematodes (albendazole derivatives). As a consequence of their pharmacokinetic behavior in monogastric species (particularly in dogs and cats), the BZDs are more effective when they are administered for several days, compared single-dose treatments. The available commercial formulations and indications for use (route of administration, dosage, and target animal species), may vary among different countries. Readers interested on any specific issue on the spectrum of activity for BZD compounds are referred to previous editions of this textbook (see Reinemeyer and Courtney, 2001). Some general considerations on the spectrum of activity for the most widely used BZD and pro-BZD compounds are summarized below.

Thiabendazole

Thiabendazole is indicated for the treatment and control of GI roundworms in horses, cattle, sheep, and goats, and the control of lungworms in sheep. Thiabendazole is administered orally at the dose range 66 to 110 mg/kg. It is also used as a fungicide for crop protection. In horses, thiabendazole is used as a single oral dose administered as a drench or by stomach tube, or as an oral paste. It is usually associated with piperazine to increase the efficacy against ascarids and immature *Oxyurus* spp. Thiabendazole is ineffective against cestodes or trematodes. In cattle, at the recommended dose rates, it is effective against adult and developing stages of *Ostertagi ostertagi* but not against stage EL_4. Thus, thiabendazole is not useful to prevent type II ostertagiasis. In pigs, thiabendazole has little efficacy against *Ascaris suum* and *Trichuris suis*.

Netobimin

The pro-BZD netobimin is formulated as a suspension for oral administration in cattle and sheep. It is indicated (7.5 mg/kg) for the removal and control of tapeworms (heads and segments)(*Moniezia expansa, M. benedeni*), adults and larval stages of abomasal worms (*Haemonchus contortus, H. placei, Trichostrongylus axei, Ostertagia ostertagi, Teladorsagia circumcincta, Marshallagia marshalli*), intestinal worms (*Trichostrongylus colubriformis, Chabertia ovina, Nematodirus spathiger, N. filicollis, N. helvetianus, Cooperia oncophora, C. punctata, Bunostomun phlebotomum, Oesophagostomum radiatum*), and lungworms (*Dictyocaulus filaria*, *D. viviparus*). Higher doses (20 mg/kg) are required for control of adult liver flukes (>14 weeks old) (*Fasciola hepatica, Fascioloides magna*) and *Thysanosoma actinioides*, and type II ostertagiasis (cattle).

Albendazole

Albendazole is formulated as a suspension for oral administration (as a drench) in cattle and sheep at the recommended dose of 7.5 and 5 mg/kg, respectively. It is indicated for the removal and control of a broad spectrum of helminth parasites, including: tapeworms (heads and segments), abomasal and intestinal nematodes (adults and fourth-stage larvae), and lungworms (adults and larval stages). Additionally, at 10 mg/kg (cattle) and 7.5 mg/kg (sheep), albendazole is active against adult liver flukes (>14 weeks old). Ovicidal activity has also been demonstrated at 8 hours posttreatment. Albendazole appeared to be effective in suppressing cyst excretion by *Giardia*-infected calves, at the oral dose of 20 mg/kg once daily for 3 days; it is thus a potential antigiardial drug for use in farm animals (Xiao et al., 1996). Similar results were observed in *Giardia*-infected dogs after oral administration (25 mg/kg) twice a day for 2 days (Barr et al., 1993).

Ricobendazole

Ricobendazole is the sulfoxide metabolite of albendazole and it is also available as a suspension for oral administration in cattle (10 mg/kg) and sheep (7.5 mg/kg). The spectrum of activity is equivalent to that described for albendazole, including the ovicidal effect. A novel ricobendazole injectable solution (15%) for subcutaneous administration to cattle is available in some countries. It has been successfully used to control abomasal and intestinal nematodes and lungworms. A 5 mg/kg dose rate is recommended to control the larval fourth stage of *O. ostertagi*. The formulation is not recommended for control of liver flukes and tapeworms. In Europe, ricobendazole is also approved for use in pheasants by feed administration (17 mg/kg during 3 days) and is mainly indicated for the control of ascarids and capillarid infections.

Febantel

Febantel, a pro-BZD compound, is used in ruminants, horses, dogs, cats, and pigs. It is formulated as a paste, suspension, or tablets for oral administration. It is used at a dose of 10 mg/kg (ruminants), 6 mg/kg (horses), 10 mg/kg (dogs and cats) and 20 mg/kg (pigs). Dogs and cats required a 3-day period of treatment. Since FBT has not anthelmintic activity, its spectrum depends on its main active metabolites fenbendazole and oxfendazole. Consequently, its spectrum is similar to these compounds.

Fenbendazole

Fenbendazole is formulated as a suspension for oral administration in cattle, sheep, and goats at the recommended dose of 10 mg/kg (cattle) and 5 mg/kg (sheep, goats). Fenbendazole is indicated for the removal and control of tapeworms (heads and segments), abomasal and intestinal nematodes (adults and fourth stage larvae), and lungworms (adults and larval stages). Fenbendazole also have ovicidal activity. Fenbendazole is effective for the treatment of *Giardia* infections in calves at an oral dose of 10 mg/kg administered once, or 5 mg/kg given every 24 hours for a 3-day period (O'Handley et al., 1997). Fenbendazole is administered orally to horses at 5 mg/kg for control of large strongyles (*Strongylus vulgaris, S. edentatus, S. equinus*), small strongyles (cyathostomes), and pinworms (*Oxyuris equi*). Higher doses (10 mg/kg) are required for ascarids (*Parascaris equorum*) control. At 10 mg/kg for 5 consecutive days, fenbendazole is indicated for control of arteritis caused by the fourth stage larvae of *S. vulgaris*, encysted mucosal cyathostomes larvae, including early (hypobiotic) and late third stages larvae. In pigs, fenbendazole is used as a powder (3 mg/kg per day for 3 consecutive days), and is 99% effective against *Ascaris suum* larvae migrating through the liver and lungs, and most GI nematodes (mature and immature) (*Metastrongylus apri, Oesophagostomun dentatum, O. quadrispinulatum, Hyostrongylus rubidus, Trichuris suis, Stephanurus dentatus*). Fenbendazole is used at 50 mg/kg daily for 3 consecutive days in dogs for removal of hookworms (*Ancylostoma caninum*), ascarids (*Toxocara canis, Toxascaris leonina*), whipworms (*Trichuris vulpis*), and tapeworms (*Taenia*). However, is not recommended for control of the cestode *Echinoccocus granulosus* or *Echinococcus multilocularis*. A 50 mg/kg dose for 3 days achieves good therapeutic effect against *Giardia* in dogs (Barr et al., 1993). The use of fenbendazole (granules) in zoo and wildlife animals has been approved by the Food and Drug Administration (USA). It is used at 10 mg/kg during 3 days, orally administered with food, and is indicated for the control of nematodes (ascarids, hookworms, and tapeworms) of Felinae (lion, tiger, puma, cheetah, leopard) and Ursidae (black bear, polar bear).

Oxfendazole

Oxfendazole is administered orally to cattle (4.5 mg/kg), sheep (5 mg/kg), and horses (10 mg/kg). Additionally, has been used in goats, dogs, and pigs. In all cases it is recommended for the control of the same parasites as its sulfide parent compound (fenbendazole). To avoid the ruminal bypass, an oxfendazole suspension has been approved for intraruminal administration in cattle. As described for albendazole and fenbendazole, oxfendazole can be used for the prevention and control of both type I and type II ostertagiasis in cattle. However, variable efficacy against stage EL_4 has been reported. A probable explanation for the observed variability in efficacy is the metabolic activity associated to the larval stage, where the highest efficacy could be expected during induction of inhibition and emergence of inhibited larvae and the lowest efficacy during the quiescent period. In horses, oxfendazole have a similar efficacy against GI nematodes, like the parent fenbendazole. Oxfendazole has been demonstrated to have activity against *Taenia solium* cysticercus in pigs after a single oral administration at 30 mg/kg (Gonzales et al., 1996), which has been proposed as a tool to interrupt the transmission cycle of this parasite, protecting people from neurocysticercosis. Additionally, in controlled efficacy tests using naturally infected pigs, this dosage regimen has been demonstrated to be effective against adult liver flukes (Ortiz et al., 2014) and adult stages of *Ascaris suum*, *Oesophagostomum* spp., *T. suis,* and *Metastrongylus* spp. (Alvarez et al., 2013).

Oxibendazole

Oxibendazole is used in the treatment of adult and larval stages of GI nematodes of pigs, cattle, sheep, and horses. It is used orally in suspension or paste at a dosage of 10 mg/kg (sheep and cattle) or 15 mg/kg (horses). A 10 mg/kg dose in horses is sufficient for removal and control of large strongyles, small strongyles, large roundworms, and pinworms.

Mebendazole

Mebendazole is administered orally to horses (8.8 mg/kg), sheep, and goats (15 mg/kg). It is also used in game birds, pigs, deer, dogs, and poultry as different types of formulations: premixes for medicated feed, pastes, tablets, granules, and drenches, all for oral administration. It is indicated for the control of large strongyles, small strongyles, large roundworms, and mature and immature larval stages of pinworms in horses. Doses of 22 mg/kg for 3 consecutive days are recommended for use in dogs for the treatment of roundworms, hookworms, whipworms, and tapeworms.

Flubendazole

Flubendazole is available as tablets, pastes, pellets, and premixes for oral administration in pigs, chickens, turkeys, and game birds. It is used at 5 mg/kg (single oral administration) and at 30 mg/kg in feed for 10 days in pigs, and is active against lungworms, roundworms, nodular worms, and whipworms. A 10-day feed period is required for control of heavy *Trichuris suis* infections. Oral treatment at 22 mg/kg for 3 consecutive days is recommended in dogs and cats for removal of common GI parasites and tapeworms. Flubendazole is used in poultry at 60 mg/kg in feed for 7 days (equivalent to 5 mg/kg/day for broilers and 3.6 mg/kg/day for laying hens). Flubendazole has ovicidal activity and work done in sheep demonstrates that flubendazole has a volume of distribution higher than those reported for albendazole and oxfendazole (Moreno et al., 2004), which may offer a new attractive alternative for use of the drug against tissue-dwelling parasites in sheep, where the presence of high drug concentrations for an extended period of time is usually crucial to achieve optimal clinical efficacy.

Routes of Administration and Drug Formulations

As discussed in Section Pharmacokinetic Behavior, BZD anthelmintic compounds are virtually insoluble in water, which limits most of the formulations to suspension, paste, granule, tablets, blocks, powder, and pellets for oral or intraruminal administration, or for administration in feed. Drench formulations are most frequently used in ruminant species, pastes are often preferred for horses, tablets for dogs and cats, and feed administration (powder) for swine and poultry. BZD are generally administered to ruminants in the form of a single oral dose. This single-dose treatment has traditionally been done by oral drench or by intraruminal injection; this latter approach is based on the design of a special syringe (intraruminal injector) that ejects the drug directly into the rumen cavity. This device is commercially available for the administration of a concentrated suspension of oxfendazole to cattle and was mainly designed to overcome the potential problems of the esophageal groove closure after oral treatment (see Section Factors Affecting the Disposition Kinetics and Efficacy of Benzimidazole Anthelmintics). To reduce the cost associated with treating large number of animals and with growing evidence that divided anthelmintic doses and prolonged administration increase anthelmintic efficacy, several methods for drug delivery have been used in the past. The incorporation of drug into feed blocks, for ingestion of small amounts over a prolonged grazing period, and the inclusion of drugs in drinking water, have been used for therapeutic and prophylactic parasite control. Convenience and labor saving are obvious with these group-medication systems, but at the same time no direct control is possible over the drug intake rate of individual animals.

The most versatile technology in anthelmintic drug delivery has been the development of ruminal devices that, when given to individual animals, can deliver drugs for an extended period of time. These controlled-release devices or boluses more readily provide the conditions for increased anthelmintic efficacy, such as prolonged exposure of parasites to sustained concentrations of active parent drugs or their metabolites. However, due to the high selection pressure, this sustained exposure may facilitate the development of drug-resistance parasite populations. After oral administration, the boluses remain in the rumen-reticulum and release the drug over a long period of time, either in a sustained or pulsatile manner. Different controlled-release systems have been developed for the delivery of BZD anthelmintics. The oxfendazole pulse release bolus (Rowlands et al., 1988) is based on principle of releasing a series of individual therapeutic doses of oxfendazole at predetermined intervals (20–21 days), which approximately coincide with the prepatent period of the major parasites nematodes of cattle, for about 4 months. This is achieved by the continuous galvanic corrosion of a magnesium alloy rod that periodically exposes an annular oxfendazole tablet to the ruminal fluid (Campbell, 1990). An intraruminal slow-release capsule which delivers, in the rumen of sheep and cattle, a low daily dose of albendazole for approximately 3 months has been designed. The device is a hollow cylinder of nonbiodegradable plastic which contains tablets of 3.85 g (sheep) and 18.46 g (cattle) of albendazole, and two external wings. After the administration, the wings spread out while the ruminal fluid starts to dissolve the first tablet, which releases the drug slowly in the rumen; a metal spring pushes six tablets toward the open end of the capsule. Following the administration of this device, albendazole metabolites were found in plasma for 90 days (cattle) and 105 days (sheep) after capsule administration (Delatour et al., 1990b). Albendazole is also available in controlled-release capsules, which contain 2.1 and 3.85 g of albendazole/capsule for use in weaner and adult sheep, respectively, showing a sustained anthelmintic action for 90 to 100 days after administration. Additionally, an ivermectin/albendazole capsule has been developed to assure protection against GI parasites susceptible to either compound (Castells et al., 2011).

Factors Affecting the Disposition Kinetics and Efficacy of Benzimidazole Anthelmintics

Several host-related factors may affect the kinetic behavior and resultant clinical efficacy of BZD compounds. Dissolution, absorption, and biotransformation are three of the most important processes affected by a series of host-related factors. Consult Chapter 4 in this text for background to these phenomena. Manipulation of the pharmacokinetic and metabolic patterns and the comprehension of different factors modulating them seem to be excellent alternatives to improve the use of BZD in ruminants.

Effect of ruminant esophageal groove closure: The ruminoreticulum is usually the first enteric chamber encountered by an orally administered drug. However, ingested fluids may partially bypass the ruminoreticulum to enter the abomasum via the omasum following closure of the reticular groove, a reflex especially developed in the nursing ruminant but inconsistently active in the adult. Thus, variable portions of a drug solution or suspension administered orally may became divided between the ruminoreticulum and abomasum, resulting in a complex absorption process, which may then contribute to unpredictable drug efficacy. Occasionally, reduced systemic availability and efficacy of BZD methylcarbamates have been found after oral in comparison with intraruminal administration (Hennessy and Prichard, 1981). A portion of the orally administered anthelmintic may bypass the rumen and rapidly enters the abomasum by closure of the esophageal groove. As a consequence, the poor absorption, due to insufficient time for dissolution of BZD suspension's particles, results in reduced plasma bioavailability of active BZD metabolites. Such an effect may indicate that the so-called "reservoir" and "slow delivery" effects of the rumen would be lost; although lag times between treatment and plasma detection of active metabolites could as a result be shorter, the overall bioavailability of active BZD metabolites and their resultant efficacy are significantly reduced. In spite of conflicting results and difficulties in assessing its practical implications, it is clear that upon spontaneous closure of the esophageal groove a portion of an oral drench dose may bypass the rumen, which consequently affects the kinetic behavior and clinical efficacy. It is likely that this phenomenon is more relevant for: (i) compounds that are activated in the rumen such as netobimin prodrug, or (ii) those BZD anthelmintics with a low solubility in abomasal fluid such as fenbendazole or albendazole. Thus, an important proportion of the dose of orally administered fenbendazole would directly reach the abomasum, whereby fenbendazole's insolubility and the short residence time of the digesta in this organ may account for both an inefficient and/or erratic absorption and a significant proportion of the dose passing down the GI tract to be eliminated in feces.

Effect of reduced GI transit time: Modified feeding management has been recommended to restore the anthelmintic action of those BZD compounds whose potency has been compromised by resistance (Alí and Hennessy, 1995). An enhanced plasma availability of oxfendazole, induced by temporary feed restriction in sheep, accounted for increased efficacy of the drug against BZD-resistant nematode strains (Alí and Hennessy, 1995). Fasting the animals prior to intraruminal treatment resulted in pronounced modifications to the absorption and disposition kinetics of albendazole metabolites in cattle; that is the administered drug appeared to be absorbed to a greater extent than in fed animals (Sánchez et al., 2000b). Starvation decreases digesta flow rates. A delayed GI transit time that decreased the rate of passage of the anthelmintic drug down the GI tract may have accounted for the enhanced absorption observed in fasted compared to fed animals (Figure 39.9). The fasting-induced changes to the kinetic behavior and quantitative tissue distribution of BZD methylcarbamates may have particular relevance to design strategies to increase activity against susceptible parasites. The increased concentration profiles of active drug (both parent albendazole and its sulfoxide metabolite) measured in tissues where target parasites are located (i.e., GI mucosa, lung tissue, etc.) is a strong scientific argument to recommend the "fasting approach" to improve parasite control in ruminants, and this is now recommended worldwide. However, fasting-induced improvement in BZDs dissolution/absorption may not be useful when a high level of drug resistance is already established in the treated nematode population (Alvarez et al., 2010).

Effect of the type of diet: The type of feed also influences the rate of passage of digesta and that of orally administered BZD drugs in ruminants and pigs, which may in turn affect drug absorption. The binding of different BZD compounds to dietary fiber substantially modified the duration of the so called "rumen reservoir" effect (Hennessy, 1993), altering the overall bioavailability of BZD and their metabolites in the bloodstream. Various reports using widely differing type of diets, according to local feeding conditions, have demonstrated the impact of feeding on the systemic availability of albendazole, fenbendazole, and oxfendazole in different ruminant species and pigs. The delayed GI transit time and lower abomasal pH in calves fed on a concentrate-based diet, compared to those grazing on pasture, facilitated the dissolution and absorption of albendazole administered intraruminally as a drug suspension in cattle (Sánchez et al., 1999). As a consequence, significantly higher C_{max} and AUC values were obtained in calves fed on the concentrate diet compared to those grazed on pasture. Furthermore, enhanced abomasal fluid levels of albendazole and albendazole sulfoxide were observed in concentrate-fed calves. Additionally, different types of diets have been shown to affect ruminal pH and to modify the microflora-mediated metabolic sulforeduction of BZD derivatives (Virkel et al., 1997), which further impacts on the disposition kinetics of these compounds in ruminants.

Effect of nutritional status and parasite infection: Because of its central position in the biotransformation and metabolic activities of the animal, the liver is vulnerable not only to damage by various foreign chemicals, microorganism, and parasites, but also to dietary induced metabolic disorders that may induce important changes on the pharmacokinetic behavior, side-effects, and expected efficacy of the chosen anthelmintic for therapy. The results reported by Sánchez et al. (1996) showed that the poor nutritional status of feed-restricted animals induced marked modifications to the pattern of albendazole biotransformation and its resultant disposition kinetics in cattle, which was likely produced by interference of the nutritionally induced biochemical changes on albendazole liver biotransformation. During both starvation and underfeeding in cattle, the hepatic concentrations of NADPH and ATP have been shown to decrease to about 60 and 40%, respectively, of their normal values in animals fed ad libitum. It is likely that

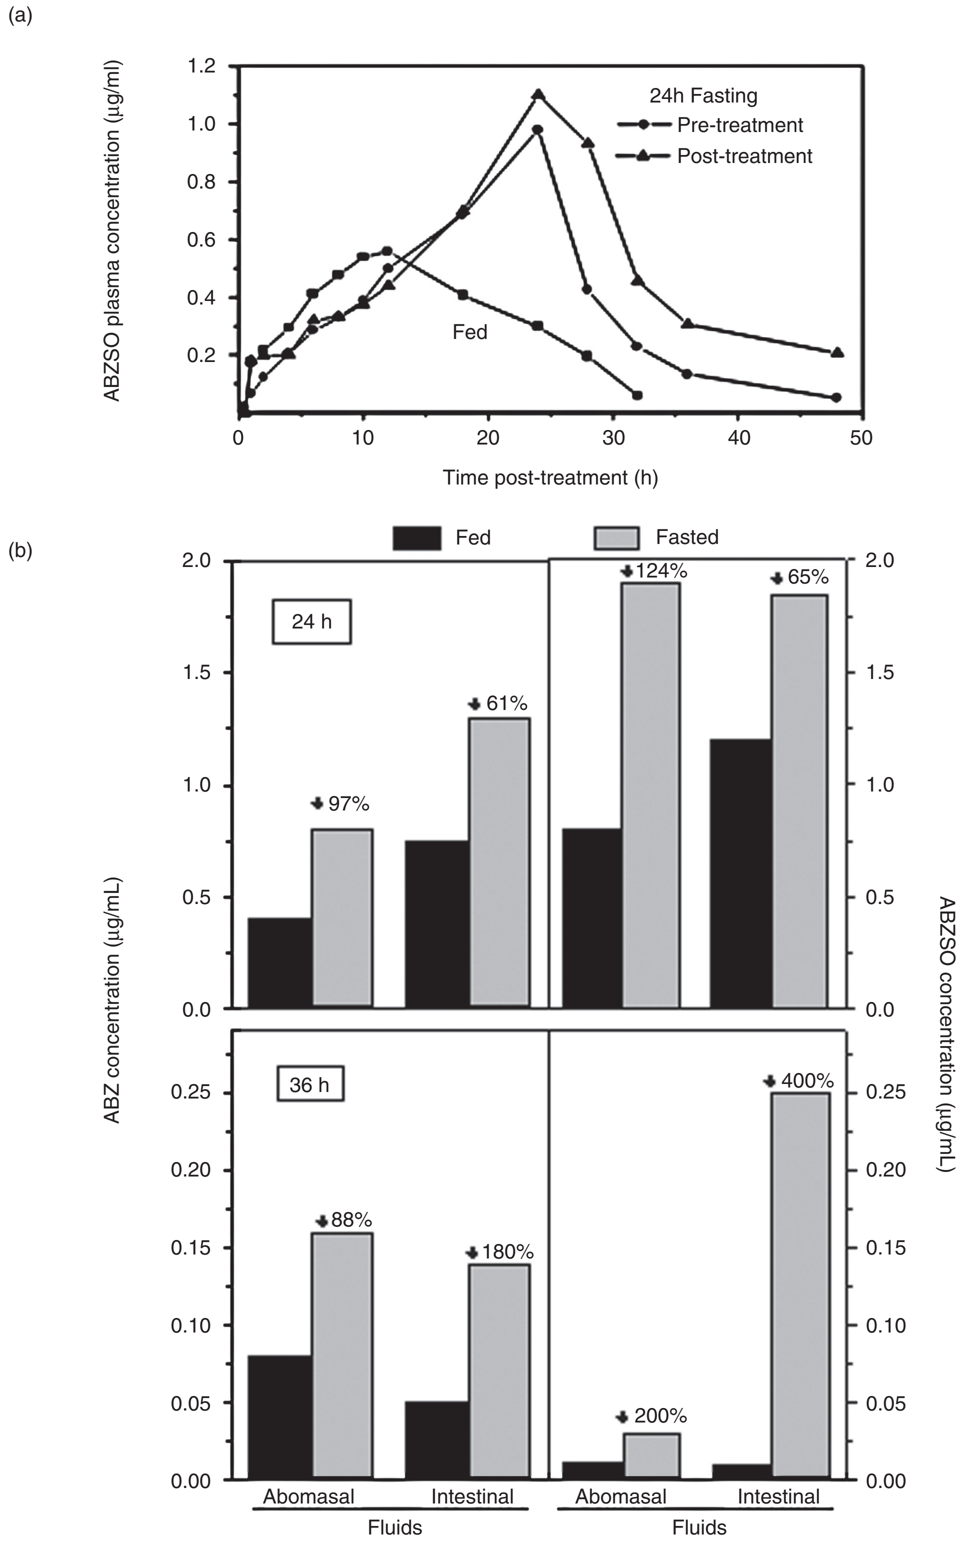


Figure 39.9 Influence of fasting on the kinetics of albendazole in cattle**.** (a) Mean albendazole sulfoxide (ABZSO) plasma concentrations obtained after the intraruminal administration of albendazole (ABZ) (10 mg/kg) to calves either fed *ad libitum* (control) or fasted during 24 h prior or after the treatment. The systemic availability of ABZSO increased between 96% (fasting pretreatment) and 118% (fasting posttreatment) in fasted compared to fed *ad libitum* calves. (b) Mean concentrations of ABZ (left panel) and ABZSO (right panel) obtained in abomasal and intestinal fluids at 24 and 36 h after the intraruminal administration of ABZ (10 mg/kg) to calves either fed *ad libitum* or fasted for 24 h pretreatment. The figures on the top of each bars represent the enhancement (percentage) on drug concentrations in the different digestive fluids observed in fasted compared to animals fed *ad libitum*. both, the decreased energy (ATP) production and the reduced NADPH availability in the liver cell may have contributed to the decreased rate of albendazole biotransformation and delayed elimination of albendazole and its metabolites observed in calves subjected to undernutrition.

The presence of the parasite itself could induce important changes to the pharmacokinetics, side-effects, and expected efficacy of the chosen BZD anthelmintic for therapy. Liver disease and parasite-mediated liver damage with alteration of liver enzyme pattern could affect biotransformation and the resultant bioavailability of anthelmintically active BZD metabolites. A reduced enzymatic activity of different liver microsomal oxidases has been reported in *Fasciola hepatica*-infected sheep (Galtier et al., 1986b), which could lead to altered patterns of drug/xenobiotic metabolism and clearance. A significant decrease in the rate of both albendazole sulfonation and albendazole sulfone elimination has been demonstrated in sheep infected with *Fasciola hepatica* (Galtier et al., 1991). These findings correlated with a 58% decrease in the rate of albendazole sulfonation by liver microsomal preparations obtained from 8-weeks infected sheep; these authors postulated that a decrease in the liver microsomal cytochrome P-450-dependent monooxygenase activity, induced by the presence of the immature liver flukes on the hepatocyte parenchyma, could likely be the cause of such a metabolic change.

Parasite-mediated inflammatory reactions with changes in mucosal permeability and in abomasal/intestinal pHs, could have an impact both on absorption and ionic-trap-mediated distribution of different BZD molecules. Elevation in abomasal pH and increased permeability of the mucosa to macromolecules has been demonstrated during abomasal parasitism. The pathophysiological changes occurring during GI parasitism may affect the absorption of BZD compounds due to modifications in the GI transit time and to the atrophy of intestinal villi. Some studies on the influence of GI parasitism on the plasma kinetics of different anthelmintic drugs have been reported. Following artificial infection with abomasal nematodes (*Teladorsagia circumcincta*, *Haemonchus contortus*), the pattern of absorption and systemic availability of fenbendazole (Marriner et al., 1985), oxfendazole (Hennessy et al., 1993b), and febantel (Debackere et al., 1993) in sheep, have been shown to be altered. On the other hand, the presence of moderate nematode infections was sufficient to identify important changes to the plasma and abomasal disposition kinetics of albendazole in both artificial and naturally infected sheep (Alvarez et al., 1997). The main modification observed in infected sheep was the elevation of the abomasal pH. The increased abomasal pH induced by the presence of the parasite, decreased the plasma/abomasum pH gradient and reduced the ionic trapping of BZD molecules in the abomasum, which may have a relevant impact on anthelmintic efficacy.

Factors Related to Pharmaceutical Formulation

As introduced in Chapter 5, pharmaceutical formulation can have a major impact on drug disposition. This is particularly true for the antiparastitic drugs presented here. The relevance of water solubility and rates of dissolution of drug particles in the GI tract lumen on the absorption and resultant pharmacokinetic behavior of BZD compounds has been extensively demonstrated. Further evidence was obtained by altering the crystalline nature of the oxfendazole molecule. The production of an amorphous form of oxfendazole by acidic treatment resulted in a marked change in water solubility from 4 μg/ml (crystalline form) to 11.3 μg/ml (amorphous form) at a pH of 7.6. The oral administration of amorphous oxfendazole resulted in a more rapid and complete absorption compared with the crystalline form. It was shown that half the dose of the amorphous oxfendazole produced equivalent efficacy to that of the normal crystalline oxfendazole. Erratic absorption and variable systemic availability can be expected after administration of low-quality BZD suspensions, where large drug particles size and poor pharmacotechnical elaboration may affect the rate of dissolution and resultant absorption in the GI tract. In fact, marked differences in the albendazole sulfoxide systemic exposure have been observed among different commercially available “generic” albendazole formulations (Suarez et al., 2011), which has been associated with the impact of the pharmaceutical quality on the dissolution of albendazole particles and resultant GI absorption.

Different pharmaceutical strategies have been investigated to overcome the limited GI dissolution and absorption of BZD anthelmintics. An injectable formulation (solution) of albendazole sulfoxide (ricobendazole) has been developed for use in cattle, exploiting its greater hydrosolubility compared to other BZD methylcarbamates (Lanusse et al., 1998). Development of more water-soluble prodrugs, albendazole loaded nanoparticles (Rodrigues et al., 1995), aqueous formulation of albendazole with cyclodextrins (Evrard et al., 2002), and surfactant-based albendazole suspensions (Virkel et al., 2003) are among other strategies used to enhance the GI absorption of BZD compounds. A marked improvement in the systemic availability of albendazole metabolites has been reported after administration of an albendazole suspension prepared with sodium lauryl sulfate in cattle (Virkel et al., 2003).

Withdrawal Times, Safety, and Toxicity

As a consequence of tissue and milk residues of BZD compounds, slaughter clearance times are required after treatment with substituted BZD and it is recommended that milk of treated animals not be used for human consumption. Withdrawal times of 3 days (meat) and 4 days (milk) are required after thiabendazole treatment in cattle. When thiabendazole is used as a single oral dose in sheep or goats, 30 days withdrawal time to slaughter time is recommended. Withdrawal times are required after albendazole treatment in beef cattle (27 days) and sheep (7–10 days). For fenbendazole given as a suspension, a period of 8 days (cattle) and 6 days (goats) of withdrawal time is needed. However, since numerous commercial products containing BZD compounds are available around the world, it is critical to check label instructions of each formulation concerning withdrawal times before its use. BZDs are not indicated in horses to be slaughtered for food purposes. Flubendazole is widely used as an anthelmintic in poultry. Its main metabolites, hydrolyzed flubendazole and reduced flubendazole have been identified in tissues of flubendazole medicated turkeys (De Ruyck et al., 2001). Concentrations of flubendazole/metabolites in eggs collected from laying hen feed with 10 and 30 mg/kg of flubendazole reached a plateau level after 10 days. The residues of flubendazole and metabolites were detected mainly in yolk, where the main metabolite, accounting for almost 60–65% of the total residue, was hydrolyzed flubendazole (Kan et al., 1998). A 7-day withdrawal time is required for flubendazole in broiler chickens. Pigs may be slaughtered for human consumption after 7 days following flubendazole treatment.

BZDs are probably one of the least toxic of the available anthelmintics. The remarkable overall safety of BZD compounds has been a major factor in their successful worldwide use. All BZDs are extremely well tolerated by domestic animals and man, and they are usually free of side-effects at therapeutic doses, even when administered to young, sick, or debilitated animals. For instance, oxfendazole does not cause detectable toxic effects at 10 times the recommended dose or at eight successive administrations of three times the therapeutic dose at 4-day intervals in ruminants and horses. Similarly, animals treated with albendazole at five to nine times the therapeutic dose, did not show any adverse events after treatment (Alvarez et al., 2012). The high safety margins, particularly for the most potent substituted BZD, is thought to be correlated with their low solubility in the GI fluids; this account for a low absorption rate and for insufficient drug reaching the bloodstream to induce toxic effect. Some members of the group, such as parbendazole, cambendazole, oxfendazole, febantel and albendazole, have been reported to be teratogenic at approximately four times their recommended doses; this limits their use in the early stages of pregnancy and sheep seem to be particularly sensitive compared to other animal species (McKellar and Scott, 1990). The administration of oxfendazole or albendazole in pregnant cows caused no increase in the incidence of congenital abnormalities in the offspring. Similar results have been reported in pigs and horses. Teratogenic effects may occur at dosages much lower than those associated with acute toxicity in target species. The observed species differences in the sensitivity to the teratogenic activity may be related to differences in the pharmacokinetics and metabolism of BZD among species. The main malformations observed following treatment at day 20 of pregnancy have been deformities of the limbs and overflexion of the carpal joints. In ewes treated with NTB at the day 17 of pregnancy, congenital malformations (skeletal and renal) and abortions were observed (Navarro et al., 1998). The types of malformations induced by flubendazole in rats after its oral administration (160 mg/kg/day for 7 consecutive days between day 8 through 15 of pregnancy) are similar to that described for parbendazole and cambendazole, and include encephalocele, meningocele, hydrocephaly, short tail, absent tail, fusion or agenesis of vertebrae, and fused ribs. The mechanism of BZD teratogenicity seems to be related to their effects on the disruption of the tubulin–microtubules equilibrium dynamics in mammalian cells and subsequent alteration of cell division. Since the main toxic effects are teratogenic, some substituted BZD molecules are contraindicated to be used in early pregnancy. Albendazole is not indicated for use during the early pregnancy in cows (45 days) and ewes (30 days). The administration of febantel as tablets in dogs and cats is not recommended in pregnant animals. However, febantel and mebendazole do not appear to exert a teratogenic effect in sheep when administered in early pregnancy.

Large doses of thiabendazole (a more soluble BZD compound) administered for a long period has been associated with anemia in dogs. In-feed flubendazole treatment in poultry does not affect egg production, fertility, and hatchability. In spite of the antimicrotubular effect of BZD molecules, different experiments involving fenbendazole, albendazole, or oxfendazole in bulls, rams, or stallions did not demonstrated adverse effects on reproductive function including spermatogenesis, testicular weight, and testosterone production (McKellar and Scott, 1990).

Imidazothiazoles

Chemistry

The first imidazothiazole anthelmintic introduced into the veterinary market (1967) was tetramisole. It is a racemic mixture of two optical isomers in equal amounts: S(−)tetramisole (L-tetramisole or levamisole) and R(+)tetramisole (D-tetramisole). Following approval and marketing of the racemic mixture, pharmaceutical scientists were able to separate D L-tetramisole into its two isomers. Further studies discovered that the anthelmintic activity of the racemic mixture was attributable almost solely to the L-isomer. Thus, by using the L-isomer alone, the dosage could be reduced by half. This also increased the safety margin since both components of tetramisole are similarly toxic but differ in anthelmintic efficacy. Currently, levamisole is the worldwide imidazothiazole compound available for use in veterinary medicine. However, in some countries, tetramisole formulations are still available. The information described below is based on the pharmacological properties of levamisole, the most extensively used drug in this chemical class.

Levamisole is the L-isomer of tetramisole. The chemical name of levamisole is (−)-2,3,5,6-tetrahydro-6-phenylimidazo[2,1-*b*] thiazole (Figure 39.10). Levamisole is an antinematodal drug with a broad range of activity in several host species. It is worldwide approved and marketed for use in cattle, sheep, swine, poultry and dogs. Levamisole is a nematodicidal compound effective against lung and GI tract nematodes but not against cestode and trematode parasites. A major advantage is its formulation flexibility rendering optional routes of administration (oral, parenteral, topical). Depending upon formulation, the drug is marketed as levamisole hydrochloride or phosphate salts (oral drenches, feed premixes and injectable preparations) and as levamisole base (pour-on). Levamisole hydrochloride, a white to pale cream crystalline powder, is highly soluble in water (1 g in 2 ml of water). This solubility facilitates the formulation of an injectable solution and a stable drench.

Mode of Action

Levamisole is a cholinergic receptor agonist and elicits spastic muscle paralysis due to prolonged activation of the excitatory nicotinic acetylcholine receptors

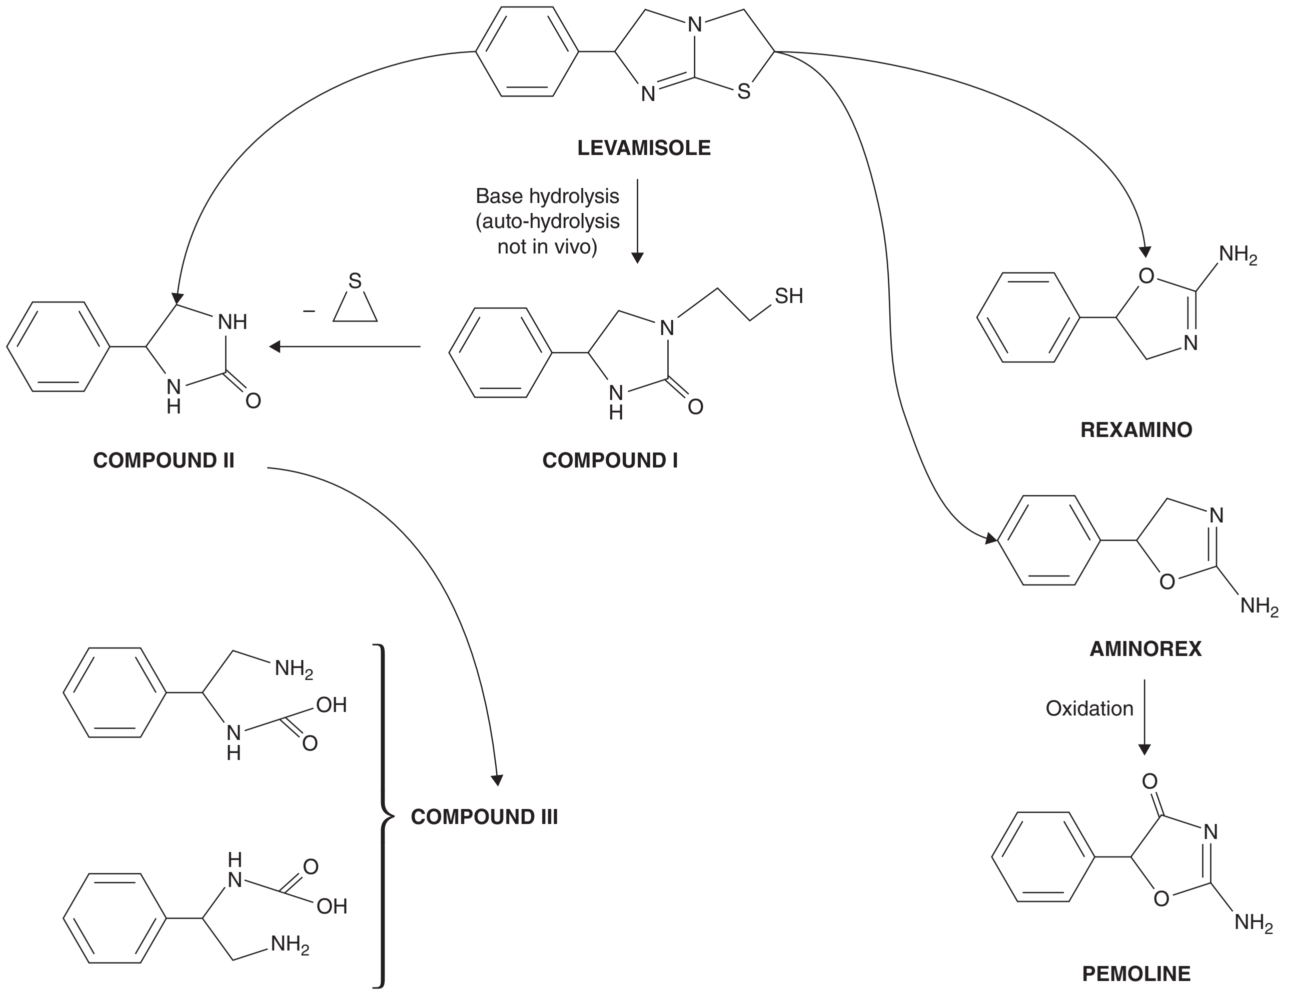

Figure 39.10 Proposed metabolic pathways of levamisole. Compound I is generated in vitro by a base hydrolysis that occurs spontaneously. Compound II, aminorex, and rexamino are formed from levamisole, while compound III and pemoline are secondary metabolites formed from compound II and aminorex, respectively.

(nAChR) on nematode body wall muscle. Levamisole's precise mode of action has been carefully studied at the single-channel level on body wall muscle preparation of *Ascaris suum* (Martin et al., 2004, 2005). Pharmacological analysis has provided evidence for subtypes of nAChR (Qian et al., 2006): an N-type (preferentially activated by nicotine and oxantel), a B-type (preferentially activated by bephenium), and an L-type (preferentially activated by levamisole and associated with levamisole resistance). Levamisole, and related compounds, also cause spastic paralysis and egg laying in *Caenorhabditis elegans*. Indeed, recordings from *Caenorhabditis elegans* body wall muscle using levamisole and nicotine as agonists have provided further evidence that there are muscle subtypes of nAChRs; these subtypes seems to have different nAChR subunit compositions. At least four subunits contribute to the levamisole receptor (Culetto et al., 2004; for further information on the nACh receptor subunit family see Rand, 2007). Its uptake in helminth parasites is considered to be mainly by a transcuticular mechanism.

Pharmacokinetics

The rate of levamisole absorption differs with the route of administration. The drug is most rapidly absorbed following intramuscular or subcutaneous injection in cattle and the highest plasma levels (>1 μg/ml) are observed at 0.5–2 hours. Several oral formulations gave similar absorption rates (T_{max}= 3 hours) and slower absorption was observed after dermal application (Bogan et al., 1982). Bioavailability differs depending on the route of administration. In sheep, the highest mean plasma concentrations were achieved after subcutaneous (3.1 μg/ml) compared to oral (0.7 μg/ml) and intraruminal (0.8 μg/ml) administration at a dose rate of 7.5 mg/kg (Bogan et al., 1982). Following pour-on administration in cattle, plasma and GI concentrations of levamisole were lower than those measured following parenteral and oral treatments (Forsyth et al., 1983), which agrees with the limited anthelmintic efficacy reported for the topical preparation. An oral bioavailability of 49% has been demonstrated in dogs, which increased to 64% when animals were fasted for a total period of 24 hours (Watson et al., 1988). In small ruminants, levamisole systemic availability has been shown to be 25–33% higher after parenteral administration compared to the oral route (Fernández et al., 1998; Sahagun et al., 2000; 2001). It has been reported (El-Kholy et al., 2006) that levamisole bioavailability in laying hens is higher at the peak egg production (88%) compared to prelaying hens (61%). Also, higher volume of distribution at steady-state (Vd_{ss}) (8–13 l/kg) and whole-body clearance (Cl_B) (2.5–3 l/kg/h) values were observed (El-Kholy et al., 2006). Garcia et al. (1994) reported that absorption was faster after the subcutaneous (T_{max} = 17 minutes) compared to the oral administration (1.12 hours) of levamisole in rabbits. The bioavailability was almost complete after subcutaneous administration, while a lower value (60%) was observed after oral administration, similar to that reported for dogs (Garcia et al., 1994). Absorption and systemic bioavailability are important because, given the mode of anthelmintic action of levamisole, the level of concentration is more important than the time of parasite exposure to the drug (Lanusse and Prichard, 1993a).

Once systemically available, levamisole is widely distributed in the organism (Vd_{ss} of 3.8, 2.75, and 2.13 l/kg in rabbits, goats, and sheep, respectively), and is recovered in tissues such as muscle, fat, kidney, and, particularly, liver at 2 hours postadministration of an oral or subcutaneous dose. In cattle, the highest milk concentrations are achieved at 1 hour postadministration. Levamisole plasma concentrations decline over a period of 6 to 8 hours, with 90% of the total dosage being excreted in 24 hours. Levamisole is rapidly and extensively metabolized to a large number of metabolites in the liver. The main metabolizing pathways appear to be oxidation, hydrolysis, and hydroxylation. Oxidation of the imidazothiazole ring is followed by oxidation to a carbonyl and hydrolysis to a thiohydantoic acid. Excretion of both levamisole and metabolites (glucuronyl or *S*-cysteinyl-glycine conjugates) is mainly in the urine (about 60%) and feces (about 30%). Unchanged levamisole accounted for 5–10% of the dose in urine and feces in cattle, sheep, and swine (Nielsen and Rasmussen, 1982; IPCS, 2003). In horses, levamisole metabolism has been well characterized because its administration to race horses led to the identification of trace amounts of prohibited substances in urine (Barker, 2009; Gutierrez et al., 2010). After oral and subcutaneous administrations to horses, levamisole is metabolized by the liver to four main metabolites (Figure 39.10): compound II, aminorex, rexamino (isomer of aminorex), and pemoline (oxidized form of aminorex) (Ho et al., 2009; Gutierrez et al., 2010). Compound II is further metabolized to the isomeric compound III (Ho et al., 2009). Plasma persistence is longer for aminorex (36 hours), rexamino, and compound II (72 hours) compared to levamisole (12 hours) (Ho et al., 2009). These metabolites are mainly excreted by the urine, where free and sulfates or glucuronide conjugated forms of unchanged and hydroxylated levamisole are also found. Also, four hydroxyl metabolites of aminorex were described (Hess et al., 2013). Aminorex is an amphetamine-like agent. Since it was found to cause pronounced vasoconstriction in the pulmonary vasculature, it was withdrawn due to cases of fatal and life-threatening pulmonary hypertension (Fishman, 1999). Pemoline is a central nervous system stimulant (Gutierrez et al., 2010).

The reported elimination half-life values are: 4–6 hours (cattle), 1.8–4 hours (dogs), 3.5–6.8 hours (pigs), 2 hours (horses), and 0.96 hours (rabbit). Levamisole is fast depleted from the animal body and tissue residues of the drug are not appreciable. Approximately 0.9% of the initial dose is found in tissues (liver and kidney) at 12–24 hours after dosing. By 7 days after dosing, levamisole is not detectable in muscle, liver, kidney, fat, blood, or urine of rats or other animals tested. Unchanged levamisole accounts only for 3% of the total tissue residues measured over a 14-day period.

Anthelmintic Spectrum

The compound has a broad spectrum of activity against mature stages of the major GI nematodes and against both mature and larval stages of lungworms. However, levamisole shows little action against arrested larval stages. Depending on the product licensed, levamisole is indicated for nematodes in cattle, sheep, goats, swine, poultry, dogs, and cats. In ruminants, levamisole has relatively good activity against abomasal nematodes, small intestinal nematodes (not particularly good against *Strongyloides* spp.), large intestinal nematodes (not *Trichuris* spp.), and lungworms. Adult stages of the nematodes that are usually covered by levamisole include: *Haemonchus* spp., *Ostertagia* spp., *Cooperia* spp., *Nematodirus* spp., *Bunostomum* spp., *Oesophagostomum* spp., *Chabertia* spp., and *Dictyocaulus vivaparus*. Levamisole is less effective against the immature forms of these parasites and is generally ineffective in cattle against arrested larval forms. In swine, levamisole is indicated for the treatment of *Ascaris suum*, *Oesophagostomum* spp., *Strongyloides ransomi, Stephanurus dentatus*, and *Metastrongylus* spp. Levamisole has been used in dogs against GI nematodes and as a microfilaricide to treat *Dirofilaria immitis* infection at a dosage of 5.5 mg/kg twice daily (12-hour interval) for 6 days (or up to 15 days for persistent microfilaremias). Because of its narrow safety margin and limited efficacy against many equine parasites, levamisole is not generally used in horses.

Formulations, Dosages, and Routes of Administration

Levamisole is administered as tablet, solution, oral drench, feed additive, subcutaneous injectable solution, or topical pour-on. In cattle, sheep, goats, and pigs, a dose of 8 mg/kg levamisole is recommended in a single oral or subcutaneous administration and 10 mg/kg as a pour-on for cattle. The bioavailability of levamisole in sheep was significantly lower after oral (42%) and intraruminal (45%) administrations compared to the injectable treatment (Bogan et al., 1982). Administration of levamisole in drinking water is used routinely only for swine and poultry. For poultry, the medicated drinking water is prepared by calculating the total amount of drug needed to provide a dose of 40 mg/kg. As the peak concentration rather than the duration of exposure is important for the anthelmintic effect of levamisole, medicated feed should be consumed fairly rapidly, otherwise efficacy may be reduced.

Injectable levamisole is preferred for use in cattle. The original, aqueous solution of levamisole hydrochloride was administered by intramuscular or subcutaneous injection. The hydrochloride, however, proved to be irritating to tissues, and intramuscular injection resulted in moderate to severe reactions at the injection site. The monobasic phosphoric acid salt of levamisole was found to be less irritating to tissues. Pour-on formulation for cattle contains 10–20% levamisole as base, which is absorbed through the skin following application to the midline of the back.

Levamisole is approved for use in dogs and cats in some countries. Tablets and oral solutions are used in dogs and cats at dose rates between 5 and 10 mg/kg. Oral treatment with 10 mg tetramisole/kg/day for 2 days removed more than 95% of ascarids (*Toxocara*, *Toxascaris*) and hookworms (*Ancylostoma*, *Uncinaria*). Levamisole is not effective against canine whipworms (*Trichuris vulpis*). Overall, levamisole remains a useful nematodicidal compound as a result of an acceptable margin of safety and spectrum of activity coupled with very low cost.

Immunomodulatory Effects

In addition to its anthelmintic activity, levamisole also may enhance immune responsiveness. This characteristic has caused considerable excitement in both veterinary and human medicine. Levamisole has proved to act as an immunomodulator in experimental models and in a number of selected human and animal immunodeficiencies with related pathology. These properties have been extensively reviewed (Koller, 1982; Blecha, 1988). The studies on its application in veterinary practice, mainly in bovine practice, have been also reviewed (Desplenter, 1983). Levamisole modulates the immune function at 2–3 mg/kg of body weight, in contrast to the greater anthelmintic doses. When administered at higher doses, levamisole may even suppress immune function. Intermittent treatment is more efficient than continuous treatment in restoring immune responsiveness. In vitro and in vivo, levamisole is able to restore to normal the major functions of effector cells of the cell-mediated immune response. This restoration is most pronounced and consistent in compromised hosts whose T-lymphocytes or phagocyte functions are below normal. Usually, an adequate immune response is not increased. The B-lymphocyte activity is not directly stimulated; the proliferative response to mitogens is not increased and there is no direct effect on antibody production. However, it should be kept in mind that the responses to levamisole are not always predictable, even if it is used in appropriate conditions. The results fluctuate between highly favorable and no effect. In cattle, for example, protective effects have been obtained in the prevention or reduction of complications associated with shipping fever (Desplenter, 1983).

Safety and Toxicity

The pharmacodynamic actions of levamisole (or tetramisole) in the host suggest that the drug exerts both muscarinic and nicotinic effects. Signs of levamisole intoxication (salivation, defecation, and respiratory distress from smooth muscle contraction) are like those observed during organophosphate poisoning. Indeed, evidence suggests that some of the toxicity of this drug may be concerned with cholinesterase inhibition, leading to manifestations of the muscarinic action of acetylcholine (ACh) (i.e., constriction of pupils and respiratory bronchioles, acceleration of GI motility, slowing of the heart rate, and other autonomic actions).

Tetramisole itself has a safety margin estimated to be two to six times the therapeutic dose of 15 mg/kg. Tetramisole is lethal to sheep at a dose of 90 mg/kg. At a dose of 45 mg/kg signs of toxicity occur. Side effects or death are more likely to occur when tetramisole is administered parenterally. The safety factor of levamisole is about twice that of the parent tetramisole compound. Levamisole is considered to be more dangerous when administered parenterally than oral or topical treatments. Intravenous administration is particularly hazardous and is never recommended. Cattle appear to be somewhat more tolerant of parenteral administration than sheep. A twofold overdose of injectable levamisole phosphate may cause about two-thirds of treated cattle to lick their lips and to develop temporary foaming of the muzzle. The pour-on formulation has been tested on several thousand cattle with only occasional dermal irritation. When given to pigs at three times the recommended dosage, levamisole causes only occasional vomiting. In such cases, the reaction is due to expulsion of the worms and should terminate in several hours. The LD_{50} of subcutaneously injected levamisole in pigs is 40 mg/kg. Simultaneous administration of pyrantel tartrate (a nicotine-like drug) enhances toxicity by lowering the levamisole LD_{50} value to 27.5 mg/kg.

Chickens tolerate tetramisole and levamisole very well. The LD_{50} for chickens is quite high (2.75 g tetramisole/kg), and minimum toxic levels of the drug in chickens exceed 640 mg/kg. In geese, however, a dosage of 300 mg/kg is known to be toxic. In chickens, therapeutic doses of levamisole (36–40 mg/kg) cause no undesirable side effects, and egg production, fertility, and hatchability are not affected adversely. Dogs and cats are much more tolerant to oral than parenteral administration of tetramisole. When given orally to dogs, doses of 20 mg/kg are well tolerated, and even 40 and 80 mg/kg are not fatal, although vomiting occurs. Subcutaneous tetramisole at 40 mg/kg is fatal to dogs in 10–15 minutes; even at 20 mg/kg, the drug causes severe reactions in dogs, although they persist for only about 20 minutes. On the basis of these findings, the oral route of administration is recommended for dogs and cats. Imidazothiazole compounds have a narrow margin of safety in horses and they are not approved for use in this species.

Levamisole should be administered within specified time periods before slaughtering swine, cattle, or sheep. A 2 to 11-day slaughter clearance time is mandated, depending on the formulation used and animal species. The identified levamisole metabolites are much less toxic than the parent compound, so the parent drug is sought in analysis of tissue samples. Since no withdrawal time has been established for dairy cows, this drug should not be administered to lactating cattle producing milk for human consumption. There are no specific contraindications in administration of levamisole with other drugs. However, other nicotine-like (e.g., pyrantel, morantel) or cholinesterase-inhibitor drugs (e.g., organophosphate, neostigmine) could theoretically enhance the toxic effects of levamisole.

Tetrahydropyrimidines

Pyrantel, introduced in 1966, was the first compound within the tetrahydropyrimidines family. It was initially used as a broad-spectrum anthelmintic against GI nematodes in sheep, and thereafter developed for use in cattle, swine, horses, dogs, and cats. Subsequently, its methyl ester analogue, morantel, was also introduced as a nematodicidal compound in the veterinary market (Figure 39.11). The newest drug in this chemical family is oxantel, an m-oxyphenol derivative of pyrantel. However, due to its cost, it is not very used in veterinary medicine.

Chemistry

Pyrantel is E-1,4,5,6-tetrahydro-1-methyl-2[2-(2-thienyl)vynil]-pyrimidin (Figure 39.11). It is formulated as tartrate, citrate, or pamoate (also known as embonate) salts. Pyrantel pamoate is practically insoluble in water and alcohol, while the tartrate salt is more water soluble. Each gram of pyrantel pamoate is approximately equivalent to 347 mg (34.7%) of the base. Pyrantel citrate is equivalent to 410 mg (41%) of the base. Pyrantel salts are relatively stable in the solid phase. Aqueous solutions are subject to photoisomerization upon exposure to light, with losing of potency. Morantel (1,4,5,6-tetrahydro-1-methyl-2-[2-(3methyl-2-thienyl)ethenyl]pyrimidine)

is mainly formulated as a tartrate salt (Figure 39.11). Each gram of the tartrate salt is equivalent to 59.5% of base activity. Oxantel is (1-methyl-2-(3-hydroxyphenyl-ethenyl)1,4,5,6-etrahydropyrimidine.

Mode of Action

Tetrahydropyrimidine compounds act selectively as agonists at synaptic and extrasynaptic nicotinic acetylcholine receptors (nAChR) on nematode muscle cells and produce contraction and spastic paralysis. As explained above (see Section Levamisole, Mode of Action), there are three different types of nAChR: L, N, and B type. Pyrantel, as levamisole, is an L-type receptor agonist, while oxantel is an N-type receptor agonist (Martin et al., 2004, 2005; Qian et al., 2006). Pyrantel and morantel are 100 times more potent than acetylcholine, although slower in initiating contraction. Pharmacological effects of pyrantel, oxantel, and morantel on the host are similar to the effects of levamisole. These anthelmintics share biological properties with acetylcholine and act essentially by mimicking the paralytic effects of excessive amounts of this natural neurotransmitter. Pyrantel, oxantel, morantel, levamisole, and diethylcarbamazine mimic this paralytic action, which is similar to the paralytic effect caused by nicotine; thus the action of these anthelmintics is referred to as nicotine-like effect. Although the chemical structures of oxantel and pyrantel are similar, oxantel offers some advantages in efficacy against *Trichuris* spp., which are due to differences in the nAChR selectivity between the molecules as well as to a difference in the dominant cholinergic receptor subtype present in these parasites compared to other intestinal nematodes (Martin et al., 2004; Kopp at al., 2009; Holden-Dye et al., 2013).

Pharmacokinetics

The pyrantel pamoate salt is poorly absorbed from the GI tract and high concentrations of the unabsorbed drug reach the lower digestive tract in dogs, cats, and horses. Pyrantel tartrate is absorbed more readily than the pamoate salt. The tartrate salt is better absorbed in pigs and dogs compared to ruminants, with peak plasma levels occurring 3–6 hours after its oral administration. Peak plasma levels occur at highly variable times in ruminants. Absorbed drug is rapidly metabolized and excreted into the feces. Pyrantel is extensively metabolized in dogs, rats, sheep, and cattle by oxidation of the thiophene ring, oxidation of the tetrapyrimidine ring, and mercapturic acid conjugation. From the in vivo radiolabel studies, it was shown that the thiophene ring underwent extensive degradation leading to acidic metabolites that are highly polar, being eliminated mainly by urine. Urinary excretion of pyrantel accounts for about 40% of the dose in the dog and 34% in the pig, about 80% of which is excreted as metabolites. The dog is the only species excreting a larger proportion of the drug/metabolites in urine compared to feces. In ruminants, urinary excretion accounts for about 25% of the original dose, much of the remainder passing unchanged in feces. In rats, urinary excretion of the drug is minor; bile is the major route of excretion of metabolites of the absorbed drug.

Morantel is negligibly absorbed in ruminants. The drug is undetectable in the bloodstream in cattle after oral treatment. Morantel is largely excreted as the unmetabolized parent compound in the feces. In a pharmacokinetic and GI compartmental distribution study in calves treated with a morantel tartrate slow-release bolus (Lanusse et al., 1992a), it was shown that the morantel peak concentration is reached at 24 hours postadministration in all GI compartments and in feces. A steady-state concentration was reached at 7–10 days posttreatment and maintained over 84–91 days in feces and in ruminal fluid, and over 98 days in abomasal and ileal fluids. These concentrations of morantel in the GI tract of cattle may account for removal of established worms with the initial high peak concentration, and prevention of establishment of incoming larvae with a plateau steady-state concentration, which is desirable to minimize selection for drug resistance.

Formulations, Dosages, and Routes of Administration

Both the tartrate and pamoate salts of pyrantel are used for parasite control in horses. Pyrantel tartrate is formulated for continuous, daily administration over prolonged periods of parasite exposure. Pyrantel pamoate can be administered in suspension or paste formulations, as well as by mixing with feed. Regardless of the method of administration, a dose of 6.6 mg pyrantel base/kg should be used. A powdered premix formulation containing 10.6% pyrantel tartrate is available for treating parasitic infections of swine via medicated feed. Overnight fasting is advised. Water should be available ad libitum during the fasting and treatment periods.

Formulations of pyrantel pamoate for dogs include suspension and tablet forms. Pyrantel pamoate is also combined with febantel and praziquantel in a tablet form for dogs. Each of the above formulations is given to dogs as a single dose. A higher dose of pyrantel pamoate (20 mg/kg) is combined with praziquantel (5 mg/kg) for cats. Administration with food delays passage through the digestive tract, prolongs contact time of the drug with parasites, and thereby increases efficacy. Mackenstedt et al. (1993) proved that preadult stages of *Toxocara canis* continuously absorbed the drug through the whole body surface and that duration of exposure to pyrantel is more important in efficacy than variations in dosage. Other formulation for dogs is a beef-based chewable form that combines ivermectin (6–12 μg/kg) for control of heartworms and pyrantel pamoate (5–10 mg/kg) for control of hookworms and ascarids. This form is administered once a month.

A sustained-release bolus of morantel tartrate for both dairy and beef cattle is widely used in Europe and has been approved in many countries in America. The drug (11.8 g morantel base) is packaged in a cylindrical trilaminate cartridge, which is administered orally by a special delivery device and is retained in the rumen/reticulum. This devise is known as the MSRT (morantel slow release trilaminate bolus). The permeable wall allows continuous release of morantel tartrate (approximately 150 mg/day) into the rumen/reticulum fluid for at least 90 days (Lanusse et al., 1992a). Administration of the MSRT bolus is recommended as preventative for larvae establishing as well as to control existing adult nematode burdens in cattle. The ultimate effect is marked reduction in pasture contamination for a prolonged period, for example 90 days of drug release and benefits that extend for another 90 days. Inhibited *Ostertagia* larvae are not killed by this method of treatment, but lowered pasture contamination helps prevent development of type II ostertagiasis.

Dosages for pyrantel tartrate are: single therapeutic dose of 12.5 mg/kg (horses), 22 mg/kg (swine), or 25 mg/kg (sheep, cattle, goats). Dosages for pyrantel pamoate are: 6.6 mg base/kg (horses), suspension and chewable form at 5 mg base/kg (dogs); tablets at 5 mg/kg for dogs over 2.2 kg but 10–15 mg/kg for dogs less than 2.2 kg body weight. Morantel tartrate is recommended for oral treatment at 8.8–9.6 mg/kg (cattle) and at 10 mg/kg (sheep).

Anthelmintic Spectrum

In general, activity of pyrantel on GI helminths in horses is independent of the method of administration or the salt, that is tartrate or pamoate. Activity of each of the two salts is characterized by consistently high efficacies. A more limited efficacy has been observed against *Strongylus edentatus*, small strongyles, and mature and immature *Oxyuris equi.* Pyrantel is >95% effective against the ileocecal tapeworm (*Anoplocephala perfoliata*) at double the regular therapeutic dosage (i.e., 13.2 mg/kg) (Reinemeyer et al., 2006).

Pyrantel is indicated for the removal or prevention of the large roundworms (*Ascaris suum*) and *Oesophagostomum* spp. in swine. They also have activity against the swine stomach worm (*Hyostrongylus rubidus*). The citrate salt of pyrantel has similar efficacy to that of pyrantel tartrate in swine. Pyrantel is used to control the following parasites in dogs: ascarids (*Toxocara cani, Toxascaris leonina*), hookworms (*Ancylostoma caninum*, *Uncinaria stenocephala*), and stomach worm (*Physalopter*). It is useful for similar parasites in cats and is considered to be safe to use, even in kittens.

Pyrantel tartrate is an effective nematodicidal in ruminants. It is effective in sheep, cattle, and goats against GI nematodes such as *Ostertagia* spp., *Haemonchus* spp., *Trichostrongylus* spp., *Nematodirus* spp., *Chabertia* spp., *Cooperia* spp., and *Oesophagostomum* spp. The drug is highly effective against mature worms and any immature stages that dwell in the lumen. Morantel is an effective nematodicidal drug for use in sheep and cattle. The salts of morantel have greater anthelmintic activity than the parent compound, pyrantel. Efficacy of morantel tartrate is quite good against adult and immature stages of *Haemonchus* spp., *Ostertagia* spp., *Trichostrongylus* spp., *Cooperia* spp., and *Nematodirus* spp. The MSRT (morantel bolus) has been designed for removal of established worms (initial peak concentration) and prevention of establishment of incoming larvae (plateau steady-state concentrations).

Safety and Toxicity

The salts of pyrantel are free of toxic effects in all animal hosts at doses up to approximately seven times the therapeutic dose. The oral LD_{50} of pyrantel tartrate is 175 mg/kg in mice and 170 mg/kg in rats. In dogs, the acute oral LD_{50} for pyrantel pamoate is greater than 690 mg/kg (138 times the therapeutic dose). In chronic toxicity studies, dogs showed ill effects when administered pyrantel tartrate at 50 or more mg/kg/day for 3 months but no adverse effects when the dosage was reduced to 20 mg/kg/day for the same period. Pyrantel is safe for horses and ponies of all ages, including sucklings, weanlings, pregnant mares, and stallions. At 20 times the recommended dose in horses, ponies and foals, pyrantel pamoate shows no adverse clinical effects or changes in blood cell values or serum chemistry parameters. Pyrantel tartrate is slightly less tolerated in horses than the pamoate salt. The tartrate salt (100 mg/kg) produced death in one of three horses. Toxic signs preceding death included a marked increase in respiration rate, profuse sweating, and incoordination. No signs of toxicosis occurred following administration of 75 mg/kg. Ataxia is seen in some cattle treated with a high dose of pyrantel tartrate (200 mg/kg). The toxic dose of the drug in pigs is not known. Pyrantel is not recommended for use in severely debilitated animals, presumably because its pharmacological action (cholinergic) may be more pronounced in these hosts.

Withdrawal periods exist for swine and ruminants designated for slaughter. Because of lack of metabolism data in horses, the drug should not be used in horses intended for human consumption. Despite its cholinergic properties, there is no clinical evidence that simultaneous use of organophosphates increases toxicity. Thus labeling for pyrantel products indicates safety for simultaneous use with insecticides, tranquilizers, muscle relaxants, and central nervous system depressants. Pyrantel is recommended not to be used concurrently with other cholinergic agonist anthelmintics (morantel or levamisole). Piperazine and pyrantel/morantel have antagonistic mechanisms of action and their combined use should be avoided.

Morantel tartrate is a safer drug than pyrantel tartrate. The oral LD_{50} of pyrantel for mice is only 170 mg/kg while that of morantel is 5 g/kg. Chronic toxicity studies indicate that doses up to four times the therapeutic dose for sheep for 60 days and 2.5 times that for cattle for 20 days produce no toxic signs. Following a single therapeutic dose (10 mg/kg) via medicated feed, the drug is barely detectable (<0.05 mg/mL) in plasma or milk of lactating cattle and goats. Negligible levels of morantel tartrate in plasma and milk following single or sustained administration allow its use in dairy animals without a milk withdrawal restriction.

Organophosphate Compounds

Organophosphate compounds had their origins as pesticides and only subsequently found use as narrow-spectrum anthelmintics. Among the organosphosphates used as anthelmintics in domestic animals are dichlorvos, trichlorfon, haloxon, naphtalophos, coumaphos, naphthalophos, and crufomate. The first two were used primarily in horses, and the latter five in ruminants. Organophosphate compounds generally remove the principal parasites of horses, pigs, and dogs but are somewhat deficient in their activity against nematodes of ruminants. Dichlorvos remains useful to control nematode parasites in monogastrics and its spectrum includes bot flies (*Gasterophilus* spp.) in horses. Overall, the organophosphates have satisfactory efficacy for nematode parasites of the abomasum (especially *Haemonchus*) and small intestine but lack satisfactory efficacy for nematodes of the large intestine (*Oesophagostomum, Chabertia*). Other more efficacious and safer antiparasitic drugs have replaced them in the last 30–35 years. However, the current widespread development of resistance to the most modern anthelmintic families has motivated the use of some organophosphate compounds as the unique alternative to control multiresistant *Haemonchus contortus*. Additional information on the pharmacological properties of the organophosphate compounds can be obtained in Chapters 8 and 43.

Heterocyclic Compounds

Phenothiazine

Phenothizaine was perhaps the first anthelmintic to demonstrate a fairly wide range of activity against GI nematodes. Phenothiazine was used extensively to control nematodes in sheep, cattle, goats, horses, and chickens since 1938. Toxicity limited its use in swine and precluded its use in dogs, cats, and humans. As stated by Reinemeyer and Courtney (2001), the emergence of phenothizaine-resistant strains of ruminant and equine nematodes in the 1960s and competition from other broad-spectrum drugs markedly reduced the utility of this compound in subsequent years. It is no longer used as an anthelmintic compound. However, readers interested on specific information on phenothiazine are referred to the previous editions of this textbook, including the 8th edition (Reinemeyer and Courtney, 2001).

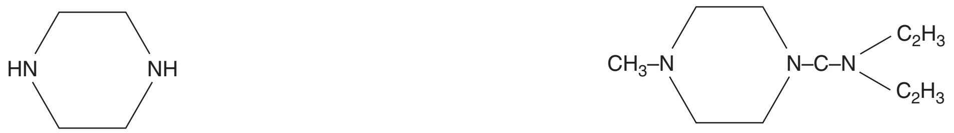
Piperazine (Diethylenediamine)

Discovered around 1900, piperazine was recognized as an anthelmintic moiety in 1954. It has good efficacy profiles against ascarid and nodular worm infections of all species of domestic animals, moderate for pinworm infections, and zero to variable for other veterinary helminths. Its low cost and wide safety margin in all domestic animals have led to its extensive worldwide use in antiparasitic therapy. Piperazine (MW 86.14 KDa) has a relatively simple chemical structure (Figure 39.12). It is a strong base, soluble in water (1 : 18), glycerol, and glycols, but only sparingly soluble in alcohol and totally insoluble in ether (Pharmaceutical Society of Great Britain, 1979). Piperazine is relatively unstable as the free base, and to improve its stability it is usually formulated as different salts such as adipate, citrate, phosphate, hexahydrate, and sulfate. Anthelmintic activity is directly related to the proportion of free base and this varies according to the salt form (e.g., adipate, 37% free base; chloride, 48%; citrate, 35%; dihydrochloride, 50–53%; hexahydrate, 44%; phosphate, 42%; sulfate, 46%)(Courtney and Roberson, 1995). Most piperazine salts are white crystalline powders that are readily soluble in water. Exceptions are adipate, which only dissolves to a maximum concentration of 5% in water, and phosphate, which is insoluble.

Piperazine is classified as a narrow-spectrum antinematodal drug since its efficacy has been only demonstrated against some specific nematodes in horses, pigs, dogs, cats, and chicken. In ruminants, this moiety is seldom used since its low efficacy against the commonest sheep abomasal parasites (*Teladorsagia circumcinta*) and other parasites located in the ruminants' small intestine. Piperazine's mode of action was initially thought to involve antagonism of cholinergic receptors located on the neuromuscular membrane. However, it is now clear that piperazine blocks transmission by hyperpolarizing nerve membranes at the neuromuscular junction leading to parasite immobilization by flaccid paralysis and consequent removal from predilection site and death. The most recent studies (Martin, 1997; Harder, 2000) demonstrate that piperazine is a selective agonist of γ-amino butyric acid (GABA) receptors, resulting in the opening of chloride channels and hyperpolarization of the membrane of the muscle cells of the nematode parasites. Mature worms are more susceptible to the action of piperazine than younger stages. Immature adults and lumen-dwelling larvae are sufficiently susceptible to be at least partially eliminated. Larval stages in host tissues, however, are relatively insusceptible. Because of subsequent larval development, repeated treatments are generally indicated within 2 weeks for carnivores and within 4 weeks for swine and horses.

Piperazine is readily absorbed through the GI tract and then extensively metabolized (60–70%). The remaining parent molecule is eliminated in urine over the 24-hour period following dosing. Piperazine base is detectable in urine as early as 30 minutes after the drug is administered. The therapeutic dose recommended for dogs and cats is 45–65 mg/kg of piperazine free base, given as a single oral administration. Efficacy has been demonstrated against *Toxocara* and *Toxoascaris*, although piperazine is ineffective against *Trichuris vulpis* (Jacobs, 1987). Treatment of nursing pups with piperazine at 2, 4, 6, and 8 weeks of age is highly effective (over 90%) in removing prenatally acquired *Toxocara canis* infections.

Dose recommended in horses, swine, and ruminants is 110 mg/kg. In horses, different piperazine salts are highly effective against ascarids, cyathostomes, and mature pinworms (*Oxyuris equi*). In foals, treatment at 8 weeks intervals is recommended for prevention of patent *Parascaris equorum* populations. Retreatment within 3–4 weeks is recommended in *Oxyuris equi* infections since piperazine has not demonstrated efficacy against immature pinworms. Single doses of piperazine are also effective (approximately 100%) against ascarids and nodular worms in swine. Retreatment 1–2 months later may



Piperazine (MW 86.1 Kda)		Diethylcarbamazine (MW 391.4 KDa)

Figure 39.12 Chemical structures and some comparative pharmacological properties of piperazine and diethylcarbamazine.

be put into practice for optimizing the efficacy against migrating larvae from tissues after the first treatment. The drug is also recommended (two doses of 32 mg/kg every 24 hours) in two successive feedings (adipate of citrate) or drinking water (hexahydrate) as a highly effective treatment against *Ascaridia galli* in poultry. However, this treatment is apparently not effective against *Heterakis gallinarum*.

Experience over many years has confirmed the safety of piperazine; it is almost nontoxic under ordinary circumstances showing a large safety margin. However, large oral doses of piperazine produce emesis, diarrhea, incoordination, and head pressing in cats and dogs. In cats, piperazine was the anthelmintic for which toxicity (confirmed or suspected) was most frequently recorded by the *Illinois Animal Poison Information Center (IAPIC)* between January 1986 and August 1988 (Lovell, 1990), although this may reflect its widespread use as much as its toxic potential. Symptoms of neurotoxicity in dogs and cats manifest as muscle tremors, ataxia, and alteration of the patient behavior within 24 hours after a daily dose of 100 mg/kg. No toxic effects have been reported in foals and horses after they were given six or seven times the therapeutic dose. However, four times the therapeutic dose may provoke digestive discomforts such us transitory diarrhea and excessive rumen gas accumulation in cattle. The therapeutic index of piperazine has been established as 3 (cats) to 6 (horses) (EMEA, 2001). Overall, piperazine remains useful as a result of its low cost, safety, and high efficacy against ascarids in different animal species.

Diethylcarbamazine Citrate

Diethylcarbamazine (MW 391.4) (Figure 39.12) is a derivative of piperazine, which is highly soluble in water, alcohol and chloroform, but insoluble in organic solvents (Pharmaceutical Society of Great Britain, 1979); it is stable in the environment. In veterinary medicine, diethylcarbamazine is formulated as tablets or chewables that are sold as a preventive for heartworm disease (*Dirofilaria immitis*) in dogs. Diethylcarbamazine should be administered daily throughout the mosquito vector season and continued for 2 months following. It is also used in combined commercial formulations also containing oxibendazole, ivermectin, or milbemycin oxime. Diethylcarbamazine has also been previously used for the treatment of lungworm infection in ruminants.

Diethylcarbamazine appears to have different mode of action compared with other antiparasitic molecules, since its microfilarial activity is absent in vitro but extensive in vivo. It has been shown that diethylcarbamazine inhibits cyclic peroxide generation from arachidonic acid (AA) breakdown, specifically through its effects on the enzymes leukotriene A4 synthetase (LTA4), prostacyclin 2 synthetase (PGI2), and prostaglandin synthetase

(PGE2). However, diethylcarbamazine has no apparent inhibitory effect on thromboxane synthetase and, therefore, cannot be classified as an inhibitor of cyclooxygenase (Martin, 1997). The microfilaria produces PGI2 and PGE2 within endothelial cells of blood vessels of infested patients. Since diethylcarbamazine can alter AA metabolism in both parasite and host, it is possible that vasoconstriction combined with amplified endothelial adhesion may be responsible for the immobilization of the microfilaria with a complementary cytotoxic action provided by host platelets and granulocytes (Martin, 1997).

After oral administration, diethylcarbamazine is readily absorbed by the GI tract, achieving maximum plasma concentration (C_{max}) at 3 hours postadministration, with a subsequent plasma detection period of approximately 48 hours. The drug is widely distributed in tissues and is metabolized in the liver by N-dealkylation and N-oxidation into four metabolites. Diethylcarbamazine is excreted in the urine either unchanged or as the N-oxide metabolite. Urinary excretion and, consequently, plasma half-life are dependent on urinary pH (Martindale, 1993). Studies with activated charcoal demonstrated that the latter significantly decreased the absorption and elimination of diethylcarbamazine by adsorption in the GI tract (Orisakwe et al., 2000). Diethylcarbamazine was shown to have generally low toxicity at the therapeutic dose of 6.6 mg/kg given as oral tablets, or 2.5 mg/kg orally given in powder form once a month, although gastric irritation was observed as a side effect in a few dogs. Diethylcarbamazine is contraindicated in dogs parasitized with adult filaria since a hypovolemic shock type reaction may occur in a small percentage (0.3–5%) of such dogs after diethylcarbamazine administration, which may lead to death within a few hours (Courtney and Roberson, 1995).

Heartworm Adulticides: Organic Arsenicals

Thiacetarsamide Sodium

This compound is a disodium salt of the *S,S*-diester of *p*-carbamoydithiobenearsonous acid with mercaptoacetic acid. It is recommended to evaluate the liver and kidney function before dosing since this arsenical compound has shown to be toxic. The plasma pharmacokinetics of thiacetarsamide has been reported in dogs after intravenous injection (2.2 mg/kg), displaying a two-compartment open model curve. A wide range in kinetic values were obtained for elimination half-life (20.5 to 83.5 minutes) and clearance rate (80.0 to 350 ml/kg/min). The mode of action is still unclear, but is presumably due to the action of the arsenic on cell glycolisis. Treatments of heartworm (*Dirofilaria immitis)* is its main therapeutic use, although a potential use in chronic fatigue syndrome associated with *Staphylococcus* spp. bacteremia has been described (Tarello, 2001). The compound does not have efficacy against circulating microfilariae. Adult worms die within a week after treatment. A dose of 3.7 mg/kg daily for 3 days produced serious side-effects in a third of the dogs tested. Side-effects at the standard dose increase with the clinical severity of the heartworm disease. Toxicity is revealed by vomiting, icterus, and orange colored urine. Dimercaprol (8.8 mg/kg/day in four divided doses) is the recommended antidote when toxic signs are manifested. Cats have demonstrated sensitivity to thiacetarsamide and its use is not recommended in this species.

Melarsomine

Melarsomine is a trivalent arsenical of the melanonyl thioarsenite family with activity against adult and 4-month-old heartworms in dogs. Melarsomine is available as a powder for mixing with sterile water before use. The FDA approved this molecule for use in dogs under hospital setting. Its mode of action is unknown. It is rapidly absorbed after intramuscular injection (2.5 mg/kg) in dogs, achieving the C_{max} at only 8 minutes postinjection. It has also been reported that melarsomine and its metabolites are free in plasma, unlike thiacetarsamide which binds to red blood cells. Arsenic plasma levels are higher and measured for a longer time after treatment with melarsomine compared to those achieved after thiacetarsamide administration.

Melarsomine is active against immature (>4 month old) and adult heartworms in dogs. Heartworm disease is preventable using the daily or monthly heartworm prevention medications. It is preferred over the use of thiacetarsamide since it can be used more safely in dogs with severe heartworm disease. The side effects provoked after injection were described as pain, swelling, and tenderness at the injection site. Coughing, gagging, depression, lethargy, lack of appetite, fever, lung congestion, and vomiting may also appear as side effects. Melarsomine has a low margin of safety and it is recommended to have an accurate weight before treating. Dimercaprol can be used as a possible antidote for reversing the toxicity within 3 hours.

Macrocyclic Lactones

Ivermectin, moxidectin, and milbemycin oxime are macrocyclic lactone compounds used to kill the tissue larval stages of *Dirofilaria immitis* in dogs and cats. The pharmacology of these exceptionally potent and highly safe compounds is fully discussed in Chapter 41.

Resistance to Anthelmintic Compounds: Molecular Basis

Perhaps it is the simplicity of treating infections with very effective drugs on a routine basis and the proven cost-effective gains in short-term productivity that has led to the predominance of chemotherapy (Zajac et al., 2000). Consequently, resistance to anthelmintic drugs has become a major problem in veterinary medicine, and threatens both livestock income and animal welfare.

Resistance is present when there is a greater frequency of individuals within a population able to tolerate doses of a compound than in a normal susceptible population of the same species. The most important feature of anthelmintic resistance is that it is inherited. Selection contributes to production of resistant populations. For each chemical class of anthelmintics, resistance to one member usually confers resistance to the other members. Genetic modifications conferring resistance are translated into different biochemical modifications that determine a reduced drug effect in the resistant cell. These molecular changes represent the pharmacological basis of the resistance phenomena. Parasites have a number of strategies to become resistant, including: (i) molecular changes affecting the capacity of the drug to accumulate at intracellular site of action (reduced uptake, enhanced active efflux, and metabolism); (ii) modified activity of parasite enzymatic systems; (iii) changes on the number, structure, and/or affinity of cellular drug receptors; and (iv) amplification of target genes to overcome the effect of the anthelmintic drug (Table 39.1).

The mechanism of action determines the time of appearance of the antiparasitic effect and the potential risk for the development of resistance to a given drug chemical class. The appearance of resistance to all the major families of broad-spectrum anthelmintics, namely benzimidazoles, imidazothiazoles (levamisole)/

Table 39.1 Summary of the main anthelmintic resistance mechanisms described in helminth parasites for the most important chemical families: macrocyclic lactones (ivermectin, moxidectin, etc.), benzimidazoles (albendazole, fenbendazole, etc.), and imidazothiazoles (levamisole)

	Macrocyclic lactones	Benzimidazoles	Imidazothiazoles
Pharmacodynamic based mechanisms	Mutations in GluCl receptor genes[a] Mutations in GABA receptor genes[b] Decreased GluCl receptor gene expression[c]	Mutations in isotype-1 β-tubulin genes[f]	Mutations in nACh receptor subunits genes[i] Different combinations of receptor subunits[j] Reduced/increased expression of nACh receptor subunit genes[k] Abbreviated isoforms of nACh receptor subunits genes[l]
Pharmacokinetic based mechanisms	P-GP overexpression[d]	P-GP overexpression[g]	P-GP overexpression[m]
	Reduced drug uptake[e]	Detoxification[h] (enhanced oxidation and drug efflux)	

GluCl, glutamate-gated chloride ion channel receptor; GABA, γ-aminobutyric acid receptor; nACh, nicotinic acetylcholine receptor; P-GP, P-glycoprotein.

[a] Mutations in *GluClα3* subunit gene in resistant *Cooperia oncophora* (Njue et al., 2004).

[b] Mutations in GABA receptor genes on a *Haemonchus contortus* isolate (Feng et al., 2002).

[c] Reduced expression levels of the GluCl receptor genes in *H. contortus* (Williamson et al., 2011), *C. oncophora,* and *Ostertagia ostertagi* (El-Abdellati et al., 2011). However, receptor gene changes appear not to be primarily involved in most cases of field resistance to macrocyclic lactones (Kotze et al., 2014).

[d] Increased drug efflux mediated by overexpression of P-GP (Williamson et al., 2011; Dicker et al., 2011; Janssen et al., 2013; De Graef et al., 2013).

[e] Changes to the anatomy and/or function of amphid sensory endings associated to reduced drug intake (Dent et al., 2000).

[f] Single nucleotide polymorphisms (SNPs) at position 200 (Kwa et al., 1994), 167 (Silvestre and Cabaret, 2002), and 198 (Ghisi et al., 2007) in the isotype-1 β-tubulin gene; SNPs at position 200 appears to be the most important regarding the BZD-resistance phenotype.

[g] Increased drug efflux mediated by overexpression of P-GP in *H. contortus* (Blackhall et al., 2008) and *Fasciola hepatica* (Alvarez et al., 2005).

[h] Increased triclabendazole detoxification in triclabendazole-resistant *F. hepatica* (Robinson et al., 2004; Alvarez et al., 2005).

[i] Mutations in nACh receptor subunit gene observed in *Caenorhabditis elegans* (Fleming et al., 1997).

[j] Different combinations of receptor subunits give raise to receptors with different pharmacological properties (Kotze et al., 2014).

[k] Reduced/increased expression of several nACh receptor subunits genes (Kopp et al., 2009; Sarai et al., 2013; Sarai et al., 2014; Romine et al., 2014).

[l] Abbreviated isoform of a nACh receptor subunits (unc-63) in *H. contortus*, *Teladorsagia circumcincta,* and *Trichostrongylus colubriformis* (Neveu et al., 2010).

[m] Increased expression of several P-GP genes in levamisole-resistant *H. contortus* larvae (Sarai et al., 2014).

tetrahydropirimidines (pyrantel, morantel), and macrocyclic lactones (avermectins, milbemicyns), has strongly motivated the development of pharmacodynamic studies in order to understand the mechanisms of drug action and resistance. Table 39.1 summarizes the main resistance mechanisms described for the most important anthelmintic chemical families.

As described in this chapter, the nematodicidal action of the benzimidazole (BZD) anthelmintics is based on their selective binding to β-tubulin, which produces subsequent disruption of the tubulin–microtubule dynamic equilibrium. BZD resistance in most trichostrongylid nematode species has been associated with the loss of high-affinity binding receptors and an alteration of the β-tubulin isoform pattern (Lubega and Prichard, 1991) based on a well-conserved mutation (single nucleotide polymorphism, SNP) at amino acid 200 (phenylalanine to tyrosine) in the parasite's isotype-1 β-tubulin gene (Kwa et al., 1994; Prichard, 2001). Others BZD-resistance-associated SNPs have been reported at codons 167 (Silvestre and Cabaret, 2002) and 198 (Ghisi et al., 2007). Additionally, modulation of the activity of transmembrane efflux pumps such as P-glycoprotein (P-GP) could also contribute to BZD resistance in trichostrongyles (Kerboeuf et al., 2003).

Levamisole acts selectively as an agonist of nicotinic acetylcholine (nACh) receptors, a transmembrane ion (Na^+ and Ca^{++}) channel, composed by five subunits. More than 30 different nACh receptor subunits has been described in parasites (Laing et al., 2013), allowing the formation of different pentameric structures. Different combinations of receptor subunits give rise to receptors that have different pharmacological properties. For example, some receptors could be sensitive to levamisole but less sensitive to pirantel and viceversa. A reduced expression of several nAChR genes has been associated with a decreased sensitivity to pyrantel in *Ancylostoma caninum* (Kopp et al., 2009). Resistance to cholinergic agonists in parasitic nematodes is polygenic and involves changes in expression of the nAChR subunits, truncated receptor subunits, and mutations in receptor subunits, as well as a possible contribution from P-GPs (Kotze et al., 2014). As an example, Sarai et al. (2014) examined subpopulations within a heterogeneous isolate of *Haemonchus contortus* and found that expression of several P-GP genes was increased in larvae showing a low level of resistance to levamisole. Furthermore, in the most resistant larvae within the population, expression of some receptor subunits genes was decreased (Sarai et al., 2014), which may indicate multiple mechanism of resistance within the same population.

It is important to note that nematodes resistant to levamisole are also resistant to the tetrahydropirimidine compounds (morantel, pyrantel). Although chemically different, morantel and pyrantel share the same mode of action with levamisole (see Figure 39.11) and therefore side resistance among them has been demonstrated and described elsewhere.

Resistance to the avermectin and milbemycin macrocyclic lactones had been related to selection of genes related to the expression of some subunits of the glutamate-gated chloride channels (GluCl) and to the drug transport P-GP (see Chapter 41 for detailed information). Additionally, genes related to a GABA-gated chloride channel subunit and β-tubulin seem to be also associated with resistance to the macrocyclic lactone compounds (Eng and Prichard, 2005). In spite of the involvement of different genes on the resistance to these molecules, not all of them may contribute to the same extent in different nematode-resistant strains. For instance, there is no evidence that polymorphism of GluCl or GABA receptors can explain the observed resistance to macrocyclic lactones compounds in most field isolates of different gastrointestinal parasites (Kotze et al., 2014).

P-GP is a member of the ATP-binding cassette (ABC) group of transporters that function as ATP-dependent efflux mechanism, enabling drugs to be expelled from cells. P-GP overexpression is a common pattern on the multidrug resistant (MDR) phenotype in different cancer cells. Overexpression of P-GP has also been implicated in the resistance of nematodes to ivermectin and moxidectin (Pouliot et al., 1997), closantel, and BZD, although the exact nature of its role has yet to be established. P-GP genes have been identified in *Caenorhabditis elegans* (at least 14 genes) (Lincke et al., 1992), in *Haemonchus contortus* (seven genes) (Sangster et al., 1999) and *Onchocerca volvulus* (two genes) (Kwa et al., 1998). In trematodes, genes encoding ABC proteins have been identified in *Schistosoma mansoni* (Bosch et al., 1994) and *Fasciola hepatica* (Reed et al., 1998). The macrocyclic lactones interact with P-GP and ivermectin has been used as an MDR-reversing agent. It has been shown that *Haemonchus contortus* resistant to ivermectin possess an increased level of P-GP expression (Xu et al., 1998) and coadministration with verapamil (an MDR-reversing agent) increase the efficacy of ivermectin and moxidectin against resistant *Haemonchus contortus* (Molento and Prichard, 1999). Phenotypic and genotypic evidences of macrocyclic lactones resistance associated with P-GP single nucleotide polymorphic sites in *Dirofilaria immitis* have been described (Bourguinat et al., 2011). The resistant filarial nematode was isolated from a dog that remained microfilariemic despite successful adulticidal treatments and repeated treatment with high doses of macrocyclic lactones. The genetic polymorphism (GG–GG), previously found to be associated with insensitivity to macrocyclic lactones in vitro, was present at a frequency of 45.3% in microfilariae that survived repeated treatments with high doses of ivermectin. The interested reader should consult Chapter 50 for a general background on pharmacogenomics applied to a wide variety of drugs.

Roundworms have sensory neurons (amphidial neurons) in their cephalic end. They are located in a pair of channels (the amphids) on either side of the pharynx (Freeman et al., 2003). The amphid dye filling defective (Dyf) gene, osm-1, and other Dyf genes, may act additively to regulate ivermectin uptake in *Caenorhabditis elegans* (Dent et al., 2000). Furthermore, Dyf mutations confer low level of resistance to ivermectin. Interestingly, the amphids structure is altered in ivermectin-resistant *Haemonchus contortus* (Dent et al., 2000), suggesting that a decreased ivermectin entry into the nematode may be other mechanism involved in drug resistance.

Anthelmintic resistance is a worldwide problem, which mainly involves nematode parasites from sheep, goats, and horses. However, there are already cattle nematodes resistant to multiple anthelmintic classes in New Zealand and South America (Fiel et al., 2000; Mejía et al., 2003; Loveridge et al., 2003; Gasbarre, 2014) and this will probably become more widespread. The rate at which anthelmintic resistance develops and spreads within a population is determined by the amount of parasites that survives the anthelmintic treatment, and contribute with their resistance genes to the next generations. This contribution is mainly influenced by parasite genetic factors, fecundity of adult parasites (generation time, offspring per generation, breeding patterns), parasites in refugia, drug features (frequency and timing of treatments, drug persistence in the host, drug dose and efficacy), rate of consumed larvae, grazing management strategy and climatic conditions. Refugia are subpopulations of parasites that are not selected by drug treatment. Organisms in the environment (larvae on pastures), which are not exposed to drugs, are in refugia. They are important because the higher the proportion of the population in refugia, the slower the selection for resistance (Sangster, 2001).

Due to the great effort involved in the development of new anthelmintic molecules, it is crucial to optimize the use of the existing ones. Increasing drug bioavailability is a pharmacological tool that cooperates with the optimization of the treatment, thereby delaying the development of anthelmintic resistance. Any pharmacological tool that allows the enhancement of a drug's systemic bioavailability will facilitate achieving higher drug concentrations to reach the sites of parasite location, for sufficient period of time, to achieve the antiparasitic effect, especially for those carrying the resistant genes. This is applicable to only those mechanisms of resistance that depend on drug concentration. A number of strategies for optimizing the use of available anthelmintics and to delay the development of resistance are under investigation, and include: (i) use of different pharmacotechnically based approaches to enhance drug absorption; (ii) enhancement of drug systemic availability by feed management (fasting before/after treatment); (iii) pharmacological modification to diminish drug efflux from resistant parasites; and (iv) modification of drug metabolism/elimination.

The use of a drug class that has been shown to be effective, or a combination of drugs with different modes of action, combined with rotation among chemical groups, and the use of as few drug treatments as possible, are the most practical and viable recommendations at present to delay the development of resistance. A major challenge is to define strategies to preserve susceptibility. Monitoring parasite populations and treating the animals when numbers reach a threshold are practical options suggested to slow down the spread of resistance (Sangster, 2001). Early detection of resistance and provision of information to farmers and their advisors are essential features of parasite control strategies aimed at preserving drug efficacy. In conclusion, integrated pharmacoparasitological research is required to minimize the impact of resistance and to obtain a complete understanding of the basic biology of the parasites and the strategies they develop for becoming resistant. Such an approach may help to identify solutions for delaying the development of resistance to the current available anthelmintics.

Nematodicidal Drug Combinations

Drug combination has been used as a useful tool to increase anthelmintic spectrum (i.e., ivermectin + clorsulon combination, which expand the spectrum of ivermectin to adult liver flukes). Furthermore, since multidrug resistance is becoming a widespread problem in farm animals, the use of drug combinations may be a practical approach to delay the development of resistance. Mixtures of drugs from different chemical families have been proposed as a valid strategy to delay the development of anthelmintic resistance (Anderson et al., 1988). Currently, a large number of combined anthelmintic drenches are available in the veterinary pharmaceutical market of important sheep-producing countries such as Australia, New Zealand, and Uruguay. Some broad-spectrum antiparasitic combinations containing albendazole, ivermectin, and levamisole (Triton®, Merial) or oxfendazole, abamectin, and levamisole (Matrix®, Ancare) have been initially introduced into the Australian and/or New Zealand markets. A multicombination drench for sheep, which combines albendazole, levamisole, closantel, and abamectin (Q-Drench®, Jurox) is approved for use in sheep in Australia.

The rationale behind using drug combinations is based on the fact that individual worms may have a lower degree of resistance to a multiple component formulation (each chemical with different mode of action/resistance) compared to that observed when a single anthelmintic molecule is used. The use of these formulations is based in a lower resistance in individual worms to a preparation with multiple components (each one with different mechanism of action) compared to the treatment with a formulation with a single active component. In an ideal situation, if an anthelmintic treatment reaches 100% of efficacy, selection of anthelmintic resistance will never occur. To achieve the highest efficacy in treated animals while the few surviving parasites are diluted into a susceptible untreated nematode population is a key principle for slowing the emergence of anthelmintic resistance in a real field situation (Dobson et al., 2001). Consequently, in farms where multiple-resistant nematode populations are present, the use of drug combinations may be an alternative to improve chemical control. Anthelmintic combinations can be used for delaying anthelmintic resistance, for specific targeting of dose-limiting species, and for managing existing resistance (Geary et al., 2012; Bartram et al., 2012). It has been reported that after the use of either a triple (levamisole + albendazole + ivermectin) combined treatment or ivermectin alone, a similar nematode control was observed (Suarez et al., 2014). Thus, the use of drug combinations to manage anthelmintic resistance may not always be an alternative to improve chemical control. Clearly, under a number of field situations, the use of anthelmintic combinations in sheep production (where anthelmintic resistance is common) may have limited sustainability. However, in cattle production systems where individual molecules still maintain their highest efficacy, the combined use of anthelmintics may be an important tool to delay resistance.

The occurrence of potential drug interactions between drug components highlights the need for deeper pharmacological-based research to identify the advantages/disadvantages of the use of combined drug preparations for anthelmintic control in livestock. A potential drug interaction refers to the possibility that one drug may alter the intensity of the pharmacological effects of another drug given concurrently. The modified effect may result from a change in the concentration of either one or both drugs in the organism (pharmacokinetic interaction) or from a change in the relationship between drug concentration and response of the organism to the drug (pharmacodynamic interaction) (Figure 39.13). There are four possible types of pharmacodynamic interactions resulting on either additive, potentiating (synergistic or supraadditive), antagonism (infraadditive), or indifferent effects. An additive effect arises when the combined effects of two drugs equal the sum of their independent activities measured separately. On the other hand, a potentiating effect is achieved when the combined effects of the drugs are significantly greater than the sum of the independent effects. A potentiating effect obtained after the coadministration of two drugs with different mode of action would be an ideal strategy to combat resistant parasites, particularly in cases of simultaneous multiple resistance, characterized by the presence of one or more worm genera resistant to all the molecules included in the combination. Since levamisole, albendazole, and ivermectin differ in their intrinsic anthelmintic mode of action, their coadministration may potentially induce a synergistic effect. Evidence of synergist action between the BZD compound fenbendazole and levamisole has

been described (Miller and Craig, 1996). Furthermore, a synergistic interaction between the novel anthelmintic derquantel and abamectin appears to occur under in vitro laboratory conditions (Puttachary et al., 2013). However, most cases of pharmacodynamic interactions between nematodicidal drugs appear to be limited to an additive effect. When multiple resistance refers to the presence of different worm genera, each one resistant to one different anthelmintic chemical family, a greater anthelmintic efficacy could be obtained by using the combination compared to that achieved by the use of each component alone, since worms surviving one molecule could be eliminated by the other. In this situation, an additive effect is apparently involved in the increased efficacy observed for the combination of albendazole sulfoxide and levamisole against BZD-resistant nematodes (Anderson et al., 1991). However, field work undertaken in Uruguay (Suarez et al., 2014) showed an equivalent efficacy against multiple-resistant *Haemonchus contortus* following the use of either a triple combined treatment (levamisole + albendazole + ivermectin) or ivermectin alone, indicating no advantageous effect of the triple combined preparation. Drug combination use requires previous diagnosis of the resistance status and it should be avoided once resistant to all the combined molecules is present, since it may have limited success reversing the resistant status.

A pharmacokinetic interaction occurs when a drug compound modifies the absorption, distribution, biotransformation, and/or elimination of another drug. As a consequence, the drug concentration at the biophase (the site of action) may be either increased or decreased. Since the higher the concentration achieved at the tissue where the parasite is located, the greater the amount of drug reaching the target parasite receptor pharmacokinetic interactions may determine modified anthelmintic efficacy. As a common feature, a drug to drug pharmacokinetic interaction can be observed after the coadministration of two or more anthelmintics, as was described in the combined administration of albendazole plus ivermectin (Alvarez et al., 2008), rafoxanide plus ivermectin (El-Banna et al., 2008), and levamisole plus albendazole plus ivermectin (Suarez et al., 2014). However, there are some reports on the absence of pharmacokinetic interactions between anthelmintics used as combinations. For instance, no differences on the plasma pharmacokinetic parameters were observed for ivermectin and closantel, administered by SC injection each alone or as a combined formulation to cattle (Cromie et al., 2006). The assessment of either the positive or negative (adverse) impact of pharmacokinetic interactions occurring between combined anthelmintic molecules needs to be elucidated before these drug mixtures are introduced into the market.

Novel Anthelmintic Drugs

The development of resistance to the existing chemical classes of broad-spectrum anthelmintics is a primary challenge for discovering new drugs to assure the long-term viability of the animal health industry (Hennessy, 1997). This situation highlights the need for developing new antiparasitic compounds with unique modes of action.

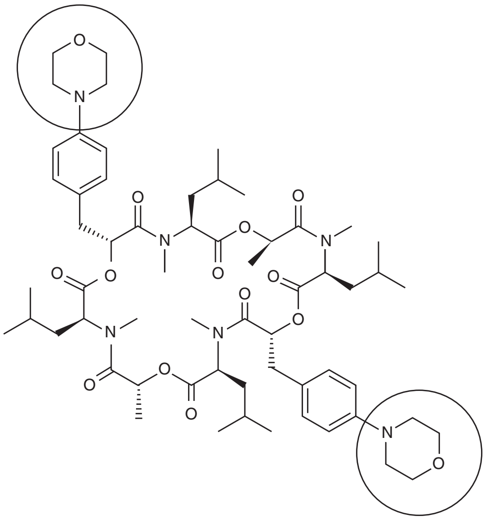
Nitazoxanide is a salycilanilide derivative of nitrothiazole. Nitazoxanide is effective against a broad spectrum of parasites and viruses infecting animals and humans, including nematodes, cestodes, trematodes, coccidian, ciliate, and flagellate protozoa. Its antiparasitic activity in domestic animals was reported a long time ago (Euzeby et al., 1980) but the efficacy pattern is too low to be attractive to be marketed in veterinary medicine. The mode of action for killing worms, protozoa, and some viruses is unknown but its comprehension may offer an opportunity for the discovery of analogs with improved potency and efficacy (Geary et al., 1999a).

The cost of developing a new class of broad-spectrum anthelmintics for use in food-producing animals is rapidly becoming prohibitive (Hennessy, 1997). However, in the last two decades numerous pharmacological studies have been carried out to generate new promising molecules with potent and unique pharmacological activity. The diketopiperazines (*marcfortine* and *paraherquamide A*), cyclic octadepsipetides (*PF1022, emodepside*), neuropeptides *(FaRP),*and the aminoacetonitrile derivatives (AADs) are among the most important novel antiparasitics. Although there is some information on the specific site of action for most of these novel molecules, the exact mechanism of action for some of them remains to be fully understood.

Paraherquamide has excellent activity against almost all of the major parasites of sheep (Shoop et al., 1990). Furthermore, oxindole alkaloids in the paraherquamide/marcfortine family exhibit broad-spectrum anthelmintic activity, including drug-resistant nematode strains (Zinser et al., 2002). Paraherquamide and related anthelmintics act as antagonists of neuronal nicotinic cholinergic receptors in both nematodes (flaccid paralysis in vitro) and mammals, and this mechanism appears to underlie both their efficacy and toxicity. 2-Desoxoparaherquamide, known as derquantel is a promising PHQ semisynthetic derivative active against both BZD and ivermectin-resistant *Haemonchus contortus* that shows markedly lower affinity for mammalian receptors than paraherquamide itself (Geary and Thompson, 2003). Derquantel is well absorbed and extensively distributed into tissues after oral administration, showing excellent anthelmintic activity against *H. contortus* (adults stages), *T. colubriformis,* and *Nematodirus* spp. (adults and L4 stages) (Little et al., 2011). In an attempt to optimize its anthelmintic activity and to decrease the selection pressure on resistant nematode strains, derquantel has been launched for use in combination with abamectin (see Chapter 41, Macrocyclic Lactones) in New Zealand, Australia, Uruguay, etc.

PF1022A (Sasaki et al., 1992), the mother compound of the class of the N-methylated 24-membered cyclooctadepsipeptides obtained as a secondary metabolite from the fungus *Mycelia sterilia*, demonstrates exceptional activity against a variety of nematodes in vitro and in vivo (Conder et al., 1995; von Samson-Himmelstjerna et al., 2000). It has been reported that PF1022A paralyses the worms by acting as GABA agonist (Chen et al., 1996) and cholinergic antagonist simultaneously (Harder et al., 2005). However, difficulties have been reported regarding its delivery to ruminant animals. Emodepside is a semisynthetic derivative of PF1022A which contains a morpholine molecule attached in the *para* position at each D-phenyllactic acid (Figure 39.14). This novel anthelmintic molecule is efficacious against a variety of GI nematodes. Emodepside acts presynaptically on a latrophilin-like receptor (depsiphilin, a putative G protein coupled receptor), located in the pharynx and body wall muscle of nematodes, which induces activation of a signal transduction cascade via Gq-alfa-protein and phospolipase-C-beta causing an increase in intracellular calcium and diacylglycerol (DAG) levels. DAG activates proteins that play a role in presynaptic vesicles function, which leads to the release of an inhibitory neuropeptide that acts postsynaptically, inducing flaccid paralysis in both pharyngeal and somatic body wall muscles of the nematode (Harder et al., 2005). Emodepside has a novel mode of anthelmintic action and is fully effective against benzimidazole, levamisole, or ivermectin-resistant nematodes of sheep and cattle (Harder et al., 2005). Emodepside is efficacious in cats against nematodes, either following its administration alone or in combination with praziquantel, which has no nematodicidal activity. At 3.0 mg/kg emodepside (spot-on formulation) has excellent activity against *Toxacara cati* (mature and immature adults), *Toxascaris leonina,* and *Ancylostoma tubaeforme* (Altreuther et al., 2005).

FMRFamide-related peptides (FaRPs) are neuropeptide with motor-modulatory activities in both arthropods and helminths. Progress in the characterization of invertebrate neuropeptide receptors has demonstrated that neuropeptide signaling may be a sound approach to identify novel endectocide molecules (Mousley et al., 2004a). FaRPs play a key role in motor coordination, which has been demonstrated in arthropod, flatworm, and nematode nervous systems (Geary et al., 1999b).



-New anthelmintic class: N-methylated 24-membered cyclo-octadepsides
-Semi-synthetic derivative of PF1022A (circled areas show the morpholine moiety in paraposition of the parent compound)
-Novel mode of action
-Broad nematocidal spectrum (larval and adult stages)
-Active against nematodes resistant to benzimidazoles, levamisole and ivermectin

-Rapid gastrointestinal (GI) absorption.

-Extensive sulphonation metabolism.

-Large monepantel and sulfone accumulation in the GI lumen.

-Low toxicity, good tolerability.

Figure 39.15 Chemical structures and main pharmacological features of the novel nematodicidal compound monepantel and its sulfone metabolite. Source: Data from Kaminsky et al., 2008; Karadzovska et al., 2009; Lifschitz et al., 2014.

FaRPs are the most potent peptides, supporting their selection as the strongest candidates for chemotherapy intervention (Mousley et al., 2004b). In association with their marked structural diversity, FaRPs within each phylum display either myoexcitatory (flatworms) or a variety of myomodulatory effects (arthropods and nematodes) that are dependent upon peptide structure (Mousley et al., 2004a). FaRPs receptors (G-protein coupled receptors) may present a suitable target for new anthelmintics (Geary et al., 1999b). FaRP receptors (or the tissues that express them) in arthropods, flatworms, and nematodes are promiscuous with respect to the interactive peptide ligands. In fact, an individual peptide from a nematode or arthropod source can activate receptors involved in motor function within the three phyla. The interphyla activity data support the concept of a single drug being able to interfere with FaRP signaling across the phyla that encompass the metazoan parasites of importance (Mousley et al., 2004a).

The molecules described here represent encouraging classes of novel antiparasitics due to their particular mechanisms of action. They may constitute a solution to control parasites resistant to the available drugs. However, a series of difficulties (toxicity, formulation, etc.) must be overcome before the most of them can reach commercial development. For instance, emodepside has been introduced in combination with praziquantel as a broad-spectrum anthelmintic for cats (spot-on) and dogs (oral) but its development for use in other animal species requires further work.

The discovery of the aminoacetonitrile derivatives (AADs) as a new chemical class of synthetic anthelmintics and the development of monepantel (Figure 39.15) are relevant steps forward in research to increase the available therapeutic options to control gastrointestinal nematodes (Kaminsky et al., 2008). A significant number of AAD compounds (about 700) were evaluated (Kaminsky et al., 2008) and finally monepantel was introduced into the veterinary pharmaceutical market. Monepantel was registered in Australia, New Zealand, and in some South American countries. Monepantel is active against larval and adult stages of gastrointestinal nematodes of sheep and cattle. It is highly effective against nematodes resistant to all the other available anthelmintic families. Monepantel effectiveness is based on a novel mechanism of action involving a unique, nematode-specific clade of the nicotinic acetylcholine receptors, which allows existing resistance to the currently available anthelmintics to be overcome. Genetic studies, conducted on the free-living nematode *Caenorhabditis elegans* and *Haemonchus contortus*, showed that monepantel acts as an agonist at the nicotinic acetylcholine receptor, producing spastic paralysis and death of the worm (Kaminsky et al., 2008; Rufener et al., 2010). After its intravenous and oral administration to sheep, monepantel is rapidly converted into a monepantel sulfone metabolite (Karadzovska et al., 2009). It has been suggested that monepantel sulfone may have the same in vitro anthelmintic activity as monepantel parent drug (Karadzovska et al., 2009). Thus, the large accumulation of both monepantel parent compound and its sulfone metabolite in different sections of sheep digestive tract (Lifschitz et al., 2014) may be relevant to the efficacy against different gastrointestinal nematodes. The activity against multidrug-resistant isolates based on a novel mode of action, its good tolerability, and low mammalian toxicity are highly favorable elements for the future of monepantel for nematodes control. However, some specific knowledge on its pharmacological behavior, as well as a highly responsible use, will be necessary to secure its maximum lifespan. The emergence of new antiparasitic compounds into the veterinary pharmaceutical market makes it necessary to have a deep understanding of their pharmacological properties in order to avoid their misuse, and thus delay the appearance of resistance

Concluding Remarks

To maximize the efficacy of anthelmintic compounds against parasites that are difficult to control in human and veterinary medicine, whilst preserving an adequate margin of safety, a complete understanding of their pharmacokinetic and metabolic patterns in the host is necessary. The complex connections among route of administration, formulation, drug physicochemical properties, and the resultant kinetic behavior need to be understood to optimize the efficacy of the existing anthelmintics. Additionally, knowledge on the differential drug pharmacological behavior among animal species and identification of different factors affecting drug activity is relevant for achieving optimal parasite control and avoiding selection for drug resistance. The technical information summarized in this chapter illustrates the complexity of the pharmacology of antinematodal compounds in the different animal species. Considering the increasing concern for the development of resistance, the use of pharmacology-based information is critical to design successful strategies for the future of parasite control. Integrated evaluation of the available knowledge on pharmacological features is required to optimize the activity and to achieve rationale use of the existing and novel nematodicidal drugs.

Anticestodal and Antitrematodal Drugs

Carlos E. Lanusse, Luis I. Alvarez, and Guillermo L. Virkel

Anticestodal Drugs

Introduction

Anticestodal drugs used to treat tapeworm infections may act as either taeniafuges or taeniacides. The former compounds facilitate tapeworm expulsion from the host, whilst the later cause the death of the tapeworm in situ. Because the cestode's scolex is capable of regenerating an entire organism, drugs that merely remove the proglottids or the whole tapeworm body but leave the scolex intact are unsatisfactory. Insufficient drug diffusion into the scolex and consecutive two or three proglottids, due to the inflammatory reaction of the intestinal mucosa, may account for such a limited cestocidal activity. The usual interval from destrobilization to patency is approximately 3 weeks, so the recommended interval for evaluating tapeworm therapy is ~3 weeks after initial drug treatment.

Tapeworm infection in farm animals may be a minor problem and usually does not require treatment with a specific cestocidal drug. Some of the broad-spectrum benzimidazole compounds used to control nematode infections (see Chapter 39) are also effective against tapeworms. However, special attention is given to the treatment of *Anoplocephala perfoliata* infections, the commonest tapeworm parasite in horses. Increasing evidence is available suggesting an association between this tapeworm and erosions around the ileocecal valve, intussusceptions, ileal impactions, and other conditions leading to recurrent episodes of intestinal colic (Gasser et al., 2005). It has been shown that oral administration of a pyrantel pamoate paste (see Chapter 39) at 13.2 mg/kg resulted in effective (96%) control of this tapeworm in naturally infected horses (Reinemeyer et al., 2006).

Treatment of tapeworm infections is also necessary in companion animals. It is medically significant that dogs and cats are definitive hosts of tapeworms whose larval stages cause zoonosis. For example, effective treatment of *Echinococcus granulosus* in dogs is extremely important since the larval stage of this tapeworm may cause hydatidosis in the intermediate hosts, primarily sheep and humans. Environmental control of intermediate hosts is also essential to prevent reinfection after treatment. The control of fleas and lice that vector *Dipylidium caninum*, and restricted access of carnivores to mammalian intermediate hosts to preclude *Taenia* infections, are essential (Reinemeyer and Courtney, 2001).

Taeniafuge compounds interfere with the ability of tapeworms to maintain their site of location in the gut. They paralyze tapeworms at least temporarily, but if tapeworms recover prior to expulsion, reattachment to the gut may occur. Thus, treatment with taeniafuges has been routinely accompanied by purgation.

Arecoline, a muscarinic agonist, induces parasite's spastic paralysis and enhances host gut motility, which facilitates tapeworm expulsion. The search for enhanced efficacy motivated the development of synthetic taeniacidal drugs that are now widely used. Many of the older antitapeworm drugs are natural organic compounds (taeniafuges). Readers interested on specific information on those older antitapeworms are referred to a previous edition of this textbook (Roberson and Courtney, 1995).

Bunamidine

Bunamidine (*N*,*N*-dibutyl-4-(hexyloxy)-1-naphthamidine) (Figure 40.1) is a taeniacidal drug that disrupts the tapeworm's tegument and reduces glucose uptake. Consequently, subtegumental tissues are exposed and destroyed by the host digestive enzymes. It is formulated as tablets (hydrochloride salt) or suspensions (hydroxynaftoate salt) for oral administration in companion animals and ruminants, respectively. The hydrochloride salt is widely used for treatment of cestode infections in dogs and cats. Bunamidine hydrochloride exhibits >90% efficacy against *Taenia* spp., *Dipylidium* spp., *Mesocestoides* spp., and *Diphyllobothrium* spp. (oral treatment at 25–50 mg/kg). However, efficacy against *D. caninum* may be erratic. Effectiveness ranging from 85.9 to 98.8% (immature stages) and 100% (mature stages) of *E. granulosus* have been reported (Andersen et al., 1975).

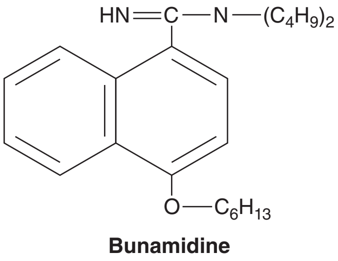

Figure 40.1 Bunamidine chemical structure.

Bunamidine prepared as a hydroxynaftoate salt is effective against *Moniezia spp.* infections in small ruminants.

Dissolution of tablets in fasted animals is improved and, therefore, subsequent contact of the drug with the parasite in the gut is enhanced, resulting in advantageous efficacy. The drug is safe because is not extensively absorbed in the duodenum and low amounts of the absorbed compound are inactivated in the liver. Administration of dissolved tablets enhances drug absorption and, consequently, the risk of systemic adverse effects such as liver damage and ventricular fibrillation. Deaths as consequence of cardiac failure have been sporadically reported within 24 hours posttreatment. Emesis and diarrhea are the most frequent adverse effects following bunamidine administration. More efficacious cestodicidal drugs have displaced bunamidine, which is no longer available in the US market.

Niclosamide

This salycilanilide compound(5-chloro-*N*-(2-chloro-4-nitrophenyl)-2-hydroxybenzamide (Figure 40.2) was widely used for treatment of cestode infections in dogs and cats from the 1960s to the 1980s. Niclosamide is highly effective against most of the tapeworm species in companion animals. However, it has poor efficacy against *Dipylidium* spp. and *E. granulosus*. This drug is also effective for the treatment of common tapeworms in ruminants such as *Moniezia* spp. and *Thysanosoma* spp. In horses it may be used for the treatment of *Anoplocephala* spp. Niclosamide's taenicidal activity involves interference with glucose absorption, inhibition of oxidative phosphorylation, and stimulation of adenosine triphosphatase activity at mitochondrial level. All these mechanisms lead to the death of the parasite and its subsequent digestion within the gut (Al-Hadiya, 2005). It may be administered as either suspension by oral or intraruminal routes in ruminants or as tablets for oral treatment in companion animals. Niclosamide administration in fasted animals increases its efficacy. Its oral administration, at doses of 100–157 mg/kg, produced only low plasma concentrations, which correlates with low gastrointestinal (GI) absorption and the well-known safety of the drug. The absorbed drug is rapidly inactivated in the liver into aminoniclosamide. Similarly to bunamidine, niclosamide has been replaced in small animal practice by modern cestocides. Interested readers are referred to a previous edition of this text (Roberson and Courtney, 1995) for a thorough discussion of the therapeutic properties of niclosamide in animal species of veterinary interest. Interestingly, niclosamide has been identified as a potential anticancer agent due to its inhibitory effects on multiple intracellular signaling pathways. The signaling molecules in those pathways may be over-expressed, constitutively active, or mutated in different cancer cells (Li et al., 2014). Consequently, a number of *in vitro* and *in vivo* studies have reported on the anticancer effectiveness of niclosamide, used either alone or in combination with other antineoplastic agents.

Praziquantel

Praziquantel is a synthetic isoquinolinepyrazine derivative: 2-(cyclohexykcarbonyl)-1,2,3,6,7,l1b-hexahydro-4*H*-pyrazino[2,1-a] isoquinolin-4-one (Figure 40.3).

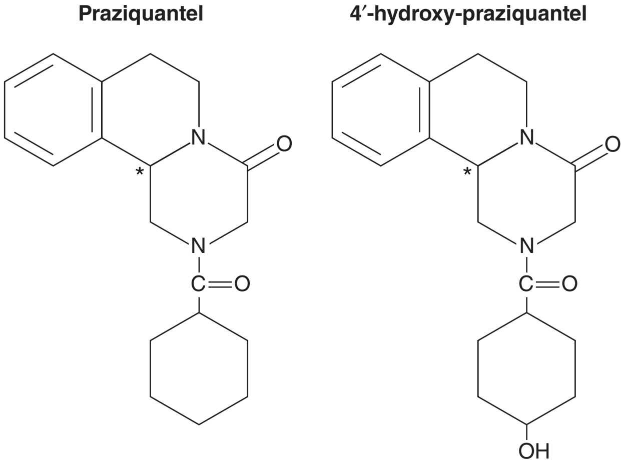

Figure 40.3 Chemical structures of praziquantel and its active metabolite (4′hydroxy-praziquantel). The asterisk (*) indicates the asymmetric (chiral) center in both molecules.

Praziquantel is highly efficacious against a variety of cestode and trematode parasites and it is widely used in both veterinary and human medicine. It has extremely high activity against adult stages of all species of tapeworms in farm and companion animals (Thomas and Gonnert, 1978). It also has good activity against larval forms of cestodes. Administration of praziquantel at 5 mg/kg in cats and dogs is completely effective against all stages of *Taenia hydatigena*, *T. pisiformis*, *T. ovis*, *T. taeniaeformis*, *D. caninum*, *Mesocestoides corti*, *E. multilocularis,* and *E. granulosus* (Thomas and Gonnert, 1978). This dose is generally recommended for elimination of the common cestode species of dogs and cats, except *Spirometra mansonoides* and *Diphyllobothrium erinacea,* which require 25 mg/kg on each of 2 consecutive days. A 10 mg/kg dosage is required to achieve good efficacy against the juvenile forms of these parasites. The drug ensures 100% elimination of *E. granulosus* in dogs and is the unique drug recommended for the treatment of this tapeworm. Oral administration of a praziquantel-containing paste (at 50 mg/kg) was effective for the control of *Dicrocoelium dendriticum* in llamas (Dadak et al., 2013). A combined formulation of febantel and praziquantel is available on the veterinary market for use in the treatment of GI nematodes and cestodes. This formulation must be administered on 3 consecutive days, at doses of 10–15 mg/kg (febantel) and 1–1.5 mg/kg (praziquantel) for adult and young dogs. A triple combination of praziquantel, pyrantel, and oxantel is also marketed as broad-spectrum dewormer for dogs and cats. Other commercial combinations used in companion animals include praziquantel plus oxibendazole, mebendazole, or fenbendazole. Combinations of praziquantel with either ivermectin (paste) or moxidectin (gel formulation) are commonly available as broad-spectrum antiparasitic formulations for use in the treatment of GI nematode and cestode infections in horses (Holm-Martin et al., 2005; Rehbein et al., 2007). A combined spot-on preparation of praziquantel and the novel compound emodepside (see Chapter 39) has been introduced into the market as a broad-spectrum anthelmintic for cats. This anthelmintic formulation has been proven to be effective for the treatment of the feline lungworm *Aelurostrongylus abstrusus* (Traversa et al., 2009).

Praziquantel is also highly effective against cestodes of ruminants. All species of *Moniezia, Stilesia,* and *Avitellina* of sheep and/or goats are eliminated by a single dose of 10–15 mg/kg. Praziquantel has been approved for tapeworm treatment in horses in different countries. It has been successfully used for the treatment of the cestode *A. perfoliata* in this species (Lyons et al., 1998). Combined formulations (gel, paste) containing ivermectin plus praziquantel are marketed for use in the treatment of GI nematode and cestode infections in horses. Most studies concerning praziquantel's mode of action have been done using the human trematode *Schistosoma mansoni* as a model parasite (Day et al., 1992). Praziquantel induces a rapid and sustained paralytic muscle contraction of the parasite and tegumental disruption. The contraction of parasite musculature is the primary effect, which is followed by a rapid vacuolization of the syncytial tegument. Muscular contraction and tegumental disruption are followed by exposure of parasite antigens, binding and penetration of host immune cells into the parasite (Martin, 1997). Metabolic changes include decrease in glucose uptake, glycogen storage, ATP content, and lactate release. All these effects are attributed either directly or indirectly to an alteration of intracellular Ca^{2+} homeostasis. Praziquantel effects are thought to be mediated by the release of intracellular stored Ca^{2+}, in addition to the increase of Ca^{2+} influx across the schistosome tegument (Day et al., 1992). Exposure and release of parasite antigens, as well as metabolic changes are attributable to the primary effect on the tegument. The exact molecular target, as well as its location within parasite tissues, remains to be completely understood. Several investigations have been focused on the beta subunit of voltage-gated Ca^{2+} channels as proposed targets for praziquantel action (Greenberg, 2005; Jeziorski and Greenberg, 2006). These channels are critical sites of extracellular Ca^{2+} influx and also play an important role in regulation of intracellular Ca^{2+} homeostasis. A variant of the beta subunit of voltage-gated Ca^{2+}channel was also found in platyhelminthes such as *Taenia solium* (Jeziorski and Greenberg, 2006). In addition, it has been demonstrated that praziquantel is an inhibitor of adenosine uptake and a relationship between this effect and praziquantel-mediated effects on Ca^{2+} influx has been hypothesized (Angelucci et al., 2007). Considering that platyhelminthes lack the biochemical pathway for purine biosynthesis, this mechanism may be involved on praziquantel antiparasitic activity. The chiral nature of praziquantel is other feature related to its pharmacological effects on the parasite. The drug has an asymmetric center in position 11b (see Figure 40.3) and, consequently, two enantiomeric forms: R(−) and S(+) praziquantel. Only the R(−) enantiomeric form has antiparasitic activity as shown by *in vitro* and *in vivo* experiments (Staudt et al., 1992; Cioli and Mattoccia, 2003; Angelucci et al., 2007).

Praziquantel can be formulated as tablet, paste, or suspension for oral administration, and as solution for SC or IM injections. Commercial formulations are racemates composed of equal parts of both praziquantel enantiomers. The pharmacokinetic behavior and metabolic fate of praziquantel has been investigated in sheep and dogs (Giorgi et al., 2001, 2003). These authors used a higher oral dose (30 mg/kg) than those recommended in these species in order to generate sufficiently high

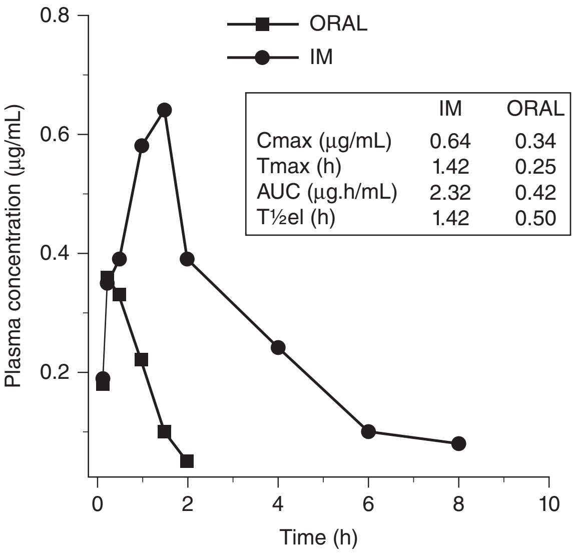

Figure 40.4 Praziquantel plasma concentration (µg/ml) profiles measured after its oral (30 mg/kg) and intramuscular (IM) (15 mg/kg) administrations to sheep. plasma concentrations for analysis. In sheep, praziquantel peak plasma concentration (C_{max}) and area under concentration-time curve (AUC) values administered by the IM route at 15 mg/kg were sixfold higher compared to those values observed following oral treatment at 30 mg/kg (Figure 40.4). The pharmacokinetics of praziquantel after its oral and IM administration was studied in water buffaloes, the major reservoirs for the human trematode *Schistosoma mansoni* in Asia (Sun and Bu, 2012); compared to the enteral administration, its relative bioavailability after the IM treatment was approximately 3.5-fold higher. It has been shown that praziquantel is completely absorbed in the GI tract in almost all species studied. Thus, its low oral bioavailability in sheep and water buffaloes is not attributed to poor GI absorption. An extensive hepatic first-pass effect accounts for the reduced praziquantel systemic availability. Liver oxidative metabolism of praziquantel in sheep resulted in the production of one hydroxylated metabolite, which might be either 11b-hydroxy- or 1-hydroxy-praziquantel (Giorgi et al., 2001). A cytochrome P450 3A isoenzyme was found to be involved in praziquantel hydroxylation in sheep liver. Conversely, the metabolite formed following praziquantel administration to dogs is 4′-hydroxy-praziquantel (Giorgi et al., 2003). This is consistent with previous studies in other species, such as rats, monkeys, and humans, in which 4′-hydroxy-praziquantel was the main metabolite (Masimirembwa and Hasler, 1994).

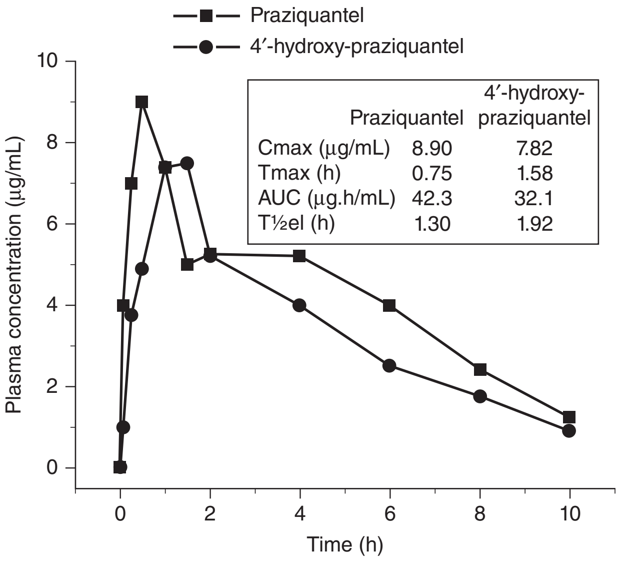

Figure 40.5 Plasma concentration profiles of praziquantel parent drug and its main hydroxylated metabolite (4′hydroxy-praziquantel) following praziquantel administration to dogs (orally, 30 mg/kg). Praziquantel and its 4′-hydroxylated metabolite were depleted in parallel from plasma in dogs, which is supported by an AUC praziquantel/4′-hydroxy-praziquantel ratio equal to 1.3 (Figure 40.5). Increased levels of the parent drug and its metabolite following administration of liquid or dry grapefruit juice combined with praziquantel to dogs has been observed. It has been shown that grapefruit juice may be an inhibitor of the P-glycoprotein transport protein and cytochrome P450-mediated oxidative drug metabolism. Grapefruit juice may interfere with either the P-glycoprotein-mediated efflux or cytochrome P450-mediated oxidation of praziquantel. Interestingly, 4′hydroxy-praziquantel has been shown to exert roughly similar pharmacological activity compared to its parent compound (Staudt et al., 1992). Metabolism of praziquantel is also stereoselective for the two enantiomers. Thus, two 4′-hydroxy-praziquantel isomers were identified in the plasma of human volunteers (Westhoff and Blaschke, 1992). It has been shown that(−)4′-hydroxy-praziquantel is far more abundant in human plasma than its respective (+)isomer. This finding is highly relevant since, *in vitro*, there is no significant difference in the pharmacological effect of (−)praziquantel and its respective (−)4′hydroxylated isomer against *S. mansoni* (Staudt et al., 1992). It has been suggested that efficacy of praziquantel in humans is mainly due to the pharmacological activity of its (−)4′hydroxylated metabolite rather than to

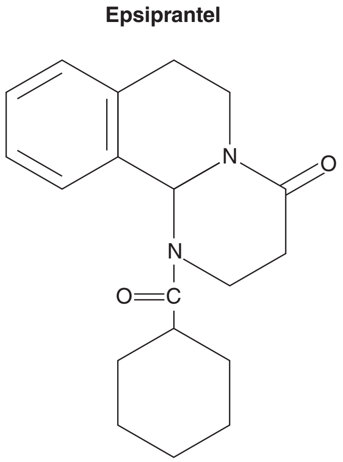

Figure 40.6 Epsiprantel chemical structure.

(−)praziquantel itself. Renal excretion is the main route of elimination of praziquantel and its metabolites.

Acute and chronic toxicity studies indicate a wide margin of safety for praziquantel. An acute, oral LD_{50} has not been established in dogs because they vomit when dosages exceed 200 mg/kg. The single therapeutic dose is 3.8–12.5 mg/kg in dogs and 4.2–12.7 mg/kg in cats. Overdoses of up to fivefold are tolerated without adverse effect. Studies in pregnant rats and rabbits detected no embryotoxic or teratogenic effects. Similar tests support the use of praziquantel in breeding and pregnant animals without restrictions.

Epsiprantel

This cestocidal compound (2-(cyclohexylcarbonyl)-oxo-1,2,3,4,6,7,8,12b-octahydropyrazino[2,1-a] [2] benzazepine) (Figure 40.6), is chemically related to praziquantel. Epsiprantel is used specifically for treatment of the common tapeworms of dogs (*D. caninum, T. pisiformis*) and cats (*D. caninum, T. taeniaeformis*). Recommended dosages are virtually 100% effective against those cestode parasites. Epsiprantel causes tegumental damage in larval and adult stages of *E. granulosus*. At a dosage of 5 mg/kg in dogs, the drug is 94% effective against immature (7-day-old) worms and more than 99% effective against mature stages (Thompson et al., 1991). At doses of 5.5 mg/kg in dogs and 2.5 mg/kg in cats, the drug was >99% effective against *E. multilocularis*, although residual worms may persist in some animals (Eckert et al., 2001). The recommended dose of 5.5 mg/kg is also 100% effective against *Taenia* spp. and 99.8% against *Dipylidium* (Corwin et al., 1989).

Similar to praziquantel, epsiprantel affects Ca^{2+} homeostasis within the parasite. The drug damages the tegument, making it vulnerable to lysis and digestion within the host's gut. Epsiprantel is only formulated for oral administration in dogs and cats. It is poorly absorbed in the GI tract and is thereby available to act against intestinal cestodes, being eliminated in feces. There are no metabolites and only 0.1% of the administered drug is eliminated by urine. The comparative pharmacological properties of praziquantel and epsiprantel are summarized in Figure 40.7.

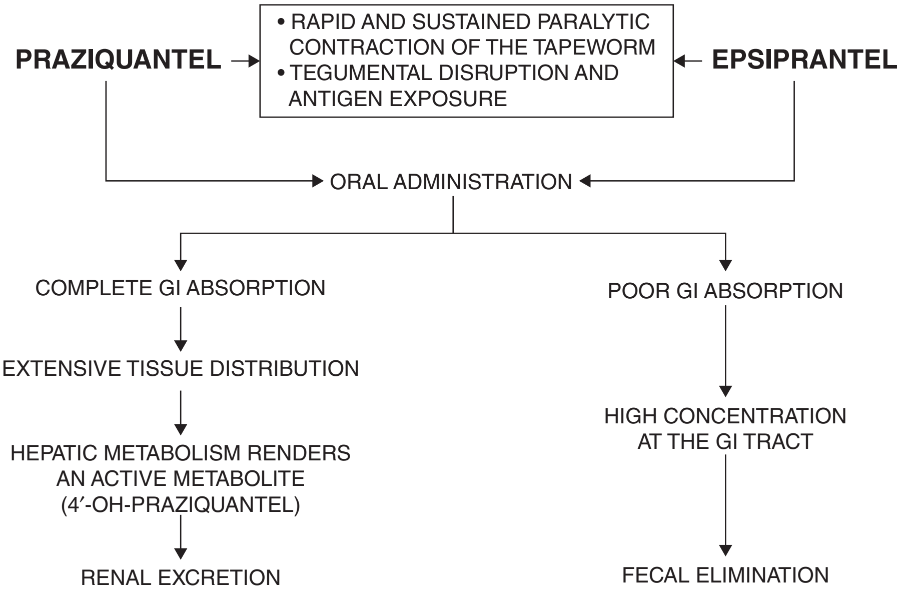
Due to its low GI absorption, epsiprantel is a safe drug. For example, cats tolerate five times the therapeutic dose of this cestocide once daily for 3 consecutive days. Emesis has been reported in cats administered 40 times the therapeutic dose daily for 4 days. Beagle puppies (7–10 weeks of age) given 100 mg/kg once (18 times the recommended dosage) exhibited no signs of toxicity. Adult dogs treated once with a 36 times overdose were not adversely affected. Emesis is the most commonly observed side effect of epsiprantel and may occur in prolonged treatments.

Antitrematodal Drugs

Introduction

Fasciolosis, caused by the cosmopolitan liver fluke *Fasciola hepatica*, is the most common and economically important disease caused by trematode parasites in domestic animals worldwide. Fasciolosis is an important zoonotic disease, particularly in underdeveloped countries (Mas-Coma, 2004). Chemotherapy, based on the use of flukicidal compounds, is the main tool to control liver flukes. Most of the antitrematodal drugs discussed herein are compounds used for the treatment of fasciolosis. The tropical counterpart of *F. hepatica* is *F. gigantica* and all drugs active against one of the species are equally effective against the other (Boray, 1986). Rumen fluke (*Paramphistomum* spp.) infections are common in cattle and sheep throughout the world. Adult flukes attach to the rumen wall and are of little consequence to the health of the animal. Large numbers of the immature stages, however, can be seriously pathogenic as they migrate within the gut lumen from the duodenum to the rumen. Intestinal paramphistomosis generally responds well to treatment with drugs that are effective against liver fluke and/or cestode infections in ruminants. Readers interested on specific issues regarding treatment of infections caused by either rumen flukes (*Paramphistomum* spp.) in sheep and cattle or lung flukes (*Paragonimus* spp.) in dogs and cats, are referred to the previous edition of this textbook (see Reinemeyer and Courtney, 2001).

The liver fluke's life cycle has several features that should be considered for a better understanding of the pharmacological properties of the antitrematodal drugs. Both immature and mature flukes damage the host liver.



PRAZIQUANTEL
• RAPID AND SUSTAINED PARALYTIC CONTRACTION OF THE TAPEWORM
• TEGUMENTAL DISRUPTION AND ANTIGEN EXPOSURE
EPSIPRANTEL
ORAL ADMINISTRATION
COMPLETE GI ABSORPTION
EXTENSIVE TISSUE DISTRIBUTION
HEPATIC METABOLISM RENDERS AN ACTIVE METABOLITE (4′-OH-PRAZIQUANTEL)
RENAL EXCRETION
POOR GI ABSORPTION
HIGH CONCENTRATION AT THE GI TRACT
FECAL ELIMINATION

Figure 40.7 Comparative pharmacodynamic and pharmacokinetic properties of the chemically related anticestodal drugs: praziquantel and epsiprantel. GI, gastrointestinal tract.

After the infective metacercariae are ingested by grazing sheep or cattle, the immature fluke emerges from its cyst, penetrates the wall of the small intestine, traverses the peritoneal cavity, and penetrates the liver capsule within 4 days of infection. During the next several weeks, immature flukes tunnel through liver tissues, feeding and increasing rapidly in size. Acute and subacute fasciolosis are most common in sheep. Both are characterized by the migration of a high number of immature flukes through the liver parenchyma causing severe hepatic hemorrhage, jaundice, and anemia. These stages are often fatal. Clinical signs of acute and subacute fasciolosis are presented within 6–8 weeks postinfection.

Antitrematodal drugs used against immature forms must achieve effective concentrations within the liver tissue. The severity of *F. hepatica* infections in sheep may be enhanced by the fluke's potential role in disseminating enteric bacteria (*Clostridium novyi*) in the liver during migration (Reinemeyer and Courtney, 2001). During the eighth week of infection, flukes begin to penetrate the main bile ducts, where they attain sexual maturity by ~10–12 weeks after infection. Adult flukes are blood-sucking parasites and penetrate within the bile ducts, causing biliary hyperplasia and progressive occlusion. The infected areas may be surrounded by connective tissue, which progressively becomes calcified. Such type of tissue reaction is most common in cattle, were fasciolosis is typically more chronic and subclinical in nature. Although adult flukes are most susceptible (or perhaps most accessible) to fasciolicidal drugs at this stage, the affected areas of the liver tissue become progressively less penetrable by therapeutic agents and consequently more difficult to treat (Reinemeyer and Courtney, 2001).

Carbohydrate and energy metabolism in helminth parasites differs from those of the mammalian host. Also, parasites exhibit a wide variation in their carbohydrate break-down pathways during their life cycle (Kita et al., 1997). Parasite metabolism uses an aerobic–anaerobic transition. In general, free-living larval stages obtain their energy from aerobic processes, whereas adult forms have mainly an anaerobic metabolism. A transition in the pathways of energy metabolism was observed in both the cytosol and mitochondria of the liver fluke *F. hepatica* (Tielens et al., 1987; Tielens, 1994). Overall, energy metabolism in the adult stages is almost completely anaerobic, and aerobic processes remain only in the tegument of the parasite, which is also one of the main absorptive surfaces for drug uptake by the fluke and may be a primary target for anthelmintic action. Studies in *F. hepatica* have shown that the transtegumental transfer mechanism is critical to achieve sufficient drug concentration at the site of action to exert its flukicidal action (Mottier et al., 2006). Thus, adult forms in the bile ducts are exposed to anthelmintics or its metabolic products eliminated by bile excretion. Although the tegument represents only 1% of the total volume of the adult parasite, the integrity of the surface plasma membrane and the tegumental syncytium is essential for the viability of the fluke. The disruption of the tegument by different mechanisms (including those involved in energy generation) may have severe consequences for the parasite because the drug would penetrate deeper and disrupt also subtegumental tissues. The surface damage will be exacerbated by the surfactant action of the bile. In addition, adult blood-sucking stages may uptake the anthelmintic drugs through the alimentary canal. In fact, most of the fasciolicides have high efficacy against adult flukes due to their extended residence in the systemic circulation as a consequence of their strong plasma protein binding (~98–99%).

Since the introduction of carbon tetrachloride for treatment of helminth infections of animals in the 1920s, numerous other compounds have been investigated for efficacy against *F. hepatica*. Carbon tetrachloride and other halogenated hydrocarbons have a narrow therapeutic index and their adverse effects (mainly hepatotoxicity) restrict their use for the treatment of fasciolosis. Based on their chemical structure, the fasciolicidal drugs can be classified into several groups:

1) *halogenated hydrocarbons* (carbon tetrachloride, hexachloroethane, tetrachlorodifluoroethane, hexachloroparaxylene);
2) *bisphenolic compounds* (hexachlorophene, bithionol), etc.;
3) *nitrophenolic compounds* (nitroxynil, disophenol, niclofolan);
4) *salicylanilides* (closantel, rafoxanide, oxyclozanide) and *brominated salicylanilides* (bromosalans);
5) *bencenesulfonamides* (clorsulon);
6) *benzimidazole* (albendazole, netobimin, luxabendazole) and *halogenated benzimidazole* (triclabendazole);
7) *phenoxyalkanes* (diamphenethide).

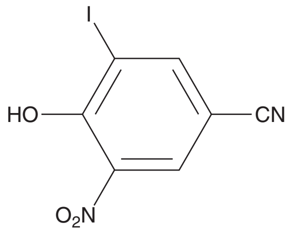
Most of the halogenated hydrocarbons, bisphenolic compounds, the nitrophenolics disophenol, and niclofolan, as well as the bromosalans, are old drugs not widely used today, and have been extensively reviewed in previous editions of this text (see Roberson and Courtney, 1995). This current chapter is focused on description of the pharmacological properties of the most currently used antitrematodal drugs. A schematic representation of the efficacy of different flukicidal drugs against immature and adult stages of *F. hepatica* is shown in Table 40.1.

Nitrophenolic Compounds

Nitroxynil

Nitroxynil (3-iodo-4-hydroxy-5-nitrobenzonitrile) (Figure 40.8) was developed in the late 1960s as an injectable fasciolicide for sheep and cattle. It is a trematodicidal compound highly effective against *F. hepatica*, which also holds activity against the abomasal nematode *Haemonchus contortus*. Nitroxynil is highly effective against adult stages of *F. hepatica* (from 8 weeks postinfection) and *F. gigantica*. Activity against earlier stages is rather erratic and it is not effective for the treatment of flukes younger than 6 weeks. Moreover, this anthelmintic is used for the control of ivermectin- and benzimidazole-resistant *H. contortus* in sheep. It is also marketed for the control of *Oesophagostomum* spp. and *Bunostomum* spp. in both sheep and cattle, and shows good activity against *Parafilaria bovicola* infections in cattle. On the contrary, nitroxynil is not effective for the treatment of paramphistomes in ruminants.

Due to the structural similarity between nitrophenols and 2,4-dinitrophenol, a known uncoupler of oxidative phosphorylation, it was assumed that nitroxynil and



Nitroxynil

Figure 40.8 Chemical structure of the nitrophenolic compound nitroxynil.

related compounds act in a similar way in the fluke. However, there is little direct evidence showing this mechanism of action for these fasciolicides. It has been shown that nitroxynil produced a rapid spastic paralysis (within 3 hours) of the fluke *in vitro* at similar concentrations to those found in the systemic circulation *in vivo* (Fairweather et al., 1984). This action was not believed to be consequence of an uncoupling effect on the oxidative phosphorylation (Fairweather and Boray, 1999). More recently, it was shown that nitroxynil causes severe disruption of the tegument of *F. hepatica*, both *in vitro* and *in vivo* (McKinstry et al., 2003). Liver flukes recovered from rats after 24 hours of nitroxynil treatment showed extensive swelling and blebbing of the tegument in both dorsal and ventral surfaces. These changes became more severe after 48 and 72 hours following nitroxynil administration and specimens recovered following these posttreatment intervals showed more widespread tegumental loss. Although the intrinsic mechanism of nitroxynil action on the parasite has not been established, it was shown that the tegument is an important target for this flukicidal drug.

Although nitroxynil can be administered orally or intraruminally (IR), it is more effective when administered by parenteral routes (SC, IM). A ruminal microflora-mediated nitroreduction may account for its low efficacy after oral or IR treatments. Solutions (25% or 34%) of nitroxynil-*N*-alkylglucamine are available in the market to be used at 10 mg/kg. SC and IM administrations provide similar efficacy against liver flukes, but the SC route has become the method of choice in practice. Local tolerance at the site of injection is satisfactory, although transitory inflammatory swellings are occasionally observed in cattle. Formulations containing nitroxynil plus ivermectin or nitroxynil in combination with ivermectin and clorsulon are marketed for SC administration in ruminants. Nitroxynil is well and rapidly absorbed after its SC administration and binds strongly to plasma proteins (~98%), mainly to albumin (Alvinerie et al., 1991). Plasma concentrations in sheep remain high within 3 days posttreatment and may be detected in the bloodstream for 60 days. Age and/or body weight-related differences on the pharmacokinetic behavior of nitroxynil were demonstrated in sheep (Moreno et al., 2010). These authors observed lower nitroxynil AUC and mean residence time (MRT) values in lambs (6–8 months old) compared to older sheep (18–20 months old). Due to its high affinity for plasma proteins, nitroxynil has low tissue distribution and, consequently, the amount of drug reaching the liver parenchyma seems to be insufficient for treatment of immature flukes at the recommended dose rate.

Nitroxynil was shown to be metabolized by hydrolysis of the cyano group to produce 3-iodo-4-hydroxy-5-nitrobenzamide and 3-iodo-4-hydroxy-5-nitrobenzoic acid in rat liver. The enzyme(s) responsible for this hydrolytic reactions was primarily localized in the cytosol (Markus and Kwon, 1994). Nitroxynil was also found to be nitroreduced in rat liver into 3-iodo-4-hydroxy-5-aminobenzonitrile (Maffei Facino et al., 1982). Further methylation of this metabolite into 3-iodo-4-methoxy-5-aminobenzonitrile was also shown. However, the inactive metabolites were not detected in the urine nor in the plasma of nitroxynil-treated sheep. Indeed, unchanged drug is likely to be the only source responsible for nitroxynil action. Due to its high plasma protein binding, it was suggested that the blood is the primary source of drug uptake via the fluke's digestive system. In addition, the levels of nitroxynil in bile are far lower than those observed in plasma, and so the uptake of this anthelmintic through the tegument would be limited (McKinstry et al., 2003). The urine is the primary route of nitroxynil elimination, although the drug is also excreted in feces and milk (it is not approved for use in dairy animals).

Animals can be slaughtered for human consumption 60 days after nitroxynil treatment. Nitroxynil also stains wool or hair yellow; thus, care must be exercised to avoid spilling. The drug is well tolerated in cattle and sheep at the therapeutic dose of 10 mg/kg. Nitroxynil side effects in these species include hyperthermia and hyperpnoea, which were associated with the uncoupling of oxidative phosphorylation in the target species and observed at higher dose levels. Doses above 40 mg/kg may be lethal.

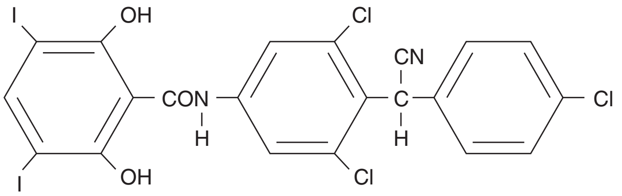
Other nitrophenolic flukicidal compounds such as disophenol and niclofolan were replaced by nitroxynil and many other newer and safer fasciolicidal drugs.

Salicylanilides

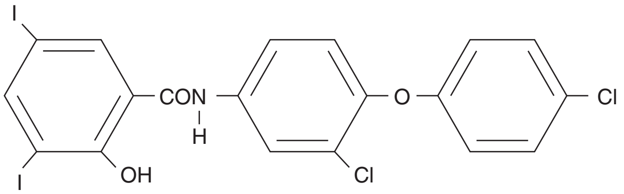
This family includes fasciolicidal drugs of similar chemical structure sharing the same mode of action. The most extensively used salicylanilides (closantel, rafoxanide, and oxyclozanide) are described here. For information on the flukicidal activity of the brominated salicylanilides (bromosdalans) readers are referred to a previous edition of this text (Roberson and Courtney, 1995).

Closantel

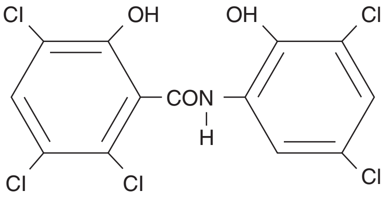
Closantel (*N*-[5-chloro-4-[(4-chlorophenyl) cyanomethyl]-2-methylphenyl]-2-hydroxy-3,5-diiodobenzamide) (Figure 40.9) is highly effective for the treatment of adult flukes and shows good activity against immature specimens aged 6–8 weeks (Table 40.1). It is not effective against earlier stages (Boray, 1986). At an oral dosage of 10 mg/kg, its efficacy is more than 92% against 8-week-old and adult *F. hepatica*. It is less active against younger stages of this parasite, that is 70–77% efficacy for 6-week-old flukes migrating in the liver. It is also effective (94.6–97.7%) against 8-week-old *Fascioloides*



Closantel



Rafoxanide



Oxyclozanide

Figure 40.9 Chemical structures of salicylanilide flukicidal compounds: closantel, oxyclozanide, and rafoxanide.

magna in sheep at oral dosages of 15 mg/kg or IM dosages of 7.5 mg/kg. However, closantel is not effective against paramphistome flukes.

Closantel is also highly effective against *H. contortus* in sheep and is used as an alternative drug for the treatment of ivermectin-, benzimidazole-, levamisole-, and morantel-resistant strains of this nematode. In addition, it is effective for the treatment of many other adult nematodes such as *Oesophagostomum* spp., *Bunostomum* spp., and *Ostertagia* spp., in both sheep and cattle. Additionally, closantel is effective against certain ectoparasites such as blood sucking lice, ticks, mites, and certain grubs of ruminants. It is also used for the treatment of the nasal bot *Oestrus ovis* in sheep. The drug can be used against the adult stage of *Ancylostoma caninum*, but is not effective against the somatic larvae of this hookworm. Closantel also has been used in horses to prevent or reduce infections of *Strongylus vulgaris* and *Gasterophilus* spp.

Closantel and other salicylanilides are uncouplers of the oxidative phosphorylation in the liver fluke. There is stronger evidence supporting this mechanism of action for these compounds than for nitrophenolic flukicides (Martin, 1997). ATP production in the mitochondria is coupled to a proton (H^+) gradient across the inner mitochondrial membrane. During the oxidative phosphorylation, electrons coming from NADH or FADH are transported through a series of protein complexes on the inner mitochondrial membrane. During this process, protons (H^+) are pumped out of the mitochondrial matrix into the space between the inner and outer mitochondrial membrane, establishing a proton gradient across the inner membrane. This proton motive force is due to the pH gradient and transmembrane electric potential being critical for ATP synthesis. Salicylanilides possesses a detachable proton (H^+) which could be shuttled across the inner mitochondrial membrane, removing the proton (H^+) gradient and uncoupling oxidative phosphorylation. Metabolic changes consequently to this mechanism include: increase in glucose uptake, decrease in glycogen content, changes in respiratory intermediates, and decrease in ATP synthesis (Fairweather and Boray, 1999).

In addition, an alternative mechanism of action of closantel has been investigated. A significant decrease in tegumental pH (6.8 to 6.5) was observed after its *in vitro* incubation with *Schistosoma mansoni* and *F. hepatica* specimens (Pax and Bennett, 1989). In fact, this fall occurred within 10 minutes after closantel addition and before any change in the production of ATP by the parasite. This effect was also observed at a lower concentration than that required to produce any reduction in ATP synthesis. It was concluded that the action of closantel is more complex than a conventional uncoupler of oxidative phosphorylation. Indeed, this anthelmintic is a membrane-active molecule capable of affecting many biochemical and physiological processes within the parasite. Closantel may also shuttle protons (H^+) across the tegumental membrane leading to a disruption of the mechanisms responsible for maintaining pH homeostasis, which are likely to reside in the tegument and excretory system (Fairweather and Boray, 1999). Closantel also induces spastic paralysis in *F. hepatica* at concentrations comparable to maximum blood levels attained *in vivo*. This effect was attributed to an increase in calcium ions in the muscle cells. It has been suggested that this neuromuscular action of closantel may take place before any disruption of energy metabolism. Consequences of the paralysis are cessation of feeding and starvation; the fluke has to draw on its energy reserves to survive and this may account, at least in part, for some of the biochemical changes observed.

Closantel is a weakly acidic molecule (pKa = 4.28) of high molecular weight (663 KDa) and extremely lipophylic. It is formulated for oral, IR, or parenteral (SC or IM) administration in ruminants. Closantel is marketed as 3.75 or 5% suspensions or solutions for oral drench or IR administration (solutions also may be used for parenteral administration). An injectable (SC) formulation of closantel and ivermectin has been licensed for use in cattle. The pharmacokinetic behavior of both anthelmintics administered as a combined product has been studied in this species (Cromie et al., 2006). The plasma availability of both active drugs in the combination was not affected by the presence of the other. Plasma profiles of closantel in the combined product were similar to those observed after administration of a reference product. On the contrary, ivermectin was absorbed and eliminated faster following its administration in the combined formulation compared with a reference product containing only ivermectin.

Closantel is well absorbed after both enteral or parenteral administrations in sheep and cattle. The recommended enteral dose rate in these species is 10 mg/kg whilst the same efficacy could be attained following its SC or IM administration at 5 mg/kg. Consequently, the oral bioavailability of closantel administered at 10 mg/kg was similar to that observed following its parenteral administration at 5 mg/kg (Michiels et al., 1987). It was shown that the bioavailability of closantel administered by the oral route was 50% lower compared to that observed following its parenteral administration. It has been shown that closantel is not subjected to any significant biodegradation by the ruminal fluid, but more than 80% of the drug was shown to be associated with the particulate phase of the abomasal digesta (Hennessy and Ali, 1997). The strong association of closantel with the particulate digesta, and the limited time available for the exchange of the drug between the particulate material and the GI fluids prior to absorption, may explain its low enteral bioavailability (Hennessy and Ali, 1997). In addition, since closantel is a weak acid, almost 99.5% of the total drug present in the intestinal lumen may be in the ionized form at the absorption site in the intestine. Altogether these observations may help to explain the incomplete GI absorption of closantel after its oral administration in ruminants. A reduction in feed intake slows the digesta flow rate and extends the residence of the drug within the GI's lumen, which accounted for increased closantel plasma and GI availabilities in sheep (Hennessy and Ali, 1997).

Closantel is extensively bound to plasma proteins (>99%), mainly albumin, and has a long terminal half-life of 14.3–14.5 days in sheep (Ali and Bogan, 1987; Hennessy, 1993). It binds specifically to ovine serum albumin at site I, the warfarin/phenylbutazone binding site of albumin, and also to invertebrate hemocyanin and hemolymph (Rothwell et al., 2000). As consequence of its high protein binding, the duration of therapeutic levels of closantel in plasma is prolonged. Thus, a single dose of closantel protects sheep against susceptible *H. contortus* reinfection for up 28 days (Hall et al., 1981). A small apparent volume of distribution (Vd) (<0.15 l/kg) indicates that the distribution of closantel to tissues (including the liver) is limited in ruminant species (Michiels et al., 1987; Swan et al., 1999). Overall, plasma albumin constitutes a reservoir from which this anthelmintic is directly available to hematophagous helminthes such as *F. hepatica* and *H. contortus*. Indeed, the blood is the primary source for the uptake of closantel via the digestive system of the parasites.

Dehalogenation in the liver renders two inactive monoiodo metabolites (3- and 5-monoiodoclosantel), although the metabolism of closantel is poor. Approximately 80–90% of the administered drug is eliminated by biliar/fecal excretion without metabolic changes. Only 10% of the administered drug was eliminated as monoiodo metabolites in sheep. Other minor routes of elimination of closantel are urine (less than 0.5% of the administered dose) and milk. In dairy cattle, approximately 1% of the administered dose was found to be excreted with the milk per day. Residual tissue concentrations are extremely low in sheep: seven to 21 times lower than the corresponding plasma concentrations. Animals may be slaughtered for human consumption 28 days after closantel treatment. In cattle, closantel concentrations in plasma were higher than those observed in milk. Similarly, mean plasma C_{max} and AUC values resulted approximately 44- and 66-fold higher, respectively, compared to those observed in milk after the oral administration of closantel (10 mg/kg) to dairy goats (Iezzi et al., 2014) (Figure 40.10). The total amount of closantel recovered in milk was equal to 1.7% of the administered dose. In this species, the calculated withdrawal time for closantel in milk was between 39 and 43 days postadministration. Moreover, closantel residual concentrations in milk subproducts, such as cheese and ricotta, were higher than those measured in the milk used for their production. For

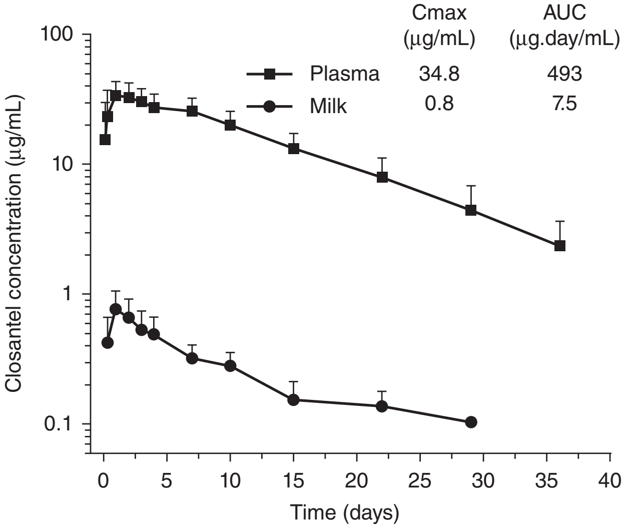


Figure 40.10 Comparative plasma and milk concentration profiles of closantel measured after its oral administration (10 mg/kg) to dairy goats. these reasons, the use of this anthelmintic in dairy animals is forbidden.

The acute toxicity resulting from single dosing of closantel in rats is characterized by hypotonia, ataxia, diarrhea, and dyspnea. Clinical signs of acute toxicity in ruminants are anorexia, labored breathing, general weakness, and decreased vision (or blindness), appearing approximately 1 week after dosing. At the lethal dose (LD_{50} in sheep = >40 mg/kg oral/IM; LD_{50} in cattle = >40 mg/kg oral and >20 mg/kg IM), anorexia, hypotonia, and quadriplegia preceded death. In short-term toxicological studies conducted in rats, male gonads and the liver were the target organs for toxicity. Some fatty deposition was observed in the liver tissue of males but not in females. Extensive reproductive studies in rams, ewes, and bulls indicate that closantel has no risk to reproductive parameters.

Rafoxanide

This anthelmintic is an halogenated salicylanilide. Its chemical formula is 3′-chloro-4′-(p-chlorophenoxy)-3,5-diiodosalicylanilide (Figure 40.9). It is an off-white crystalline powder and is commercially formulated for use as a bolus or as a drenching suspension, which may be also used for IR administration. Rafoxanide was developed in 1969 and subsequently has been used extensively worldwide against fasciolosis and haemonchosis in sheep and cattle. Its principal use is as an adulticide for *F. hepatica* and *F. gigantica*. A single therapeutic dose (7.5 mg/kg) in sheep provides nearly 100% for 12-week-old flukes of *F. hepatica*, 86–99% for 6-week-old flukes, and 50–98% for 4-week-old specimens of this parasite. At elevated doses (10–15 mg/kg), rafoxanide shows high activity against 4-week-old flukes (Boray, 1986). The same dosages reach similar efficacies against *F. hepatica* in cattle. The reliable efficacy of this drug against 4- and 6-week-old flukes gives rafoxanide an advantage over strictly adulticidal drugs in the treatment of acute fasciolosis. In this case, the administration might be repeated after 3 weeks to eliminate maturing flukes that may have escaped the earlier treatment. In addition, this anthelmintic is also indicated for the treatment of haemonchosis, bunostomosis, and sheep nasal bots (*Oestrus ovis*). The mode of action of rafoxanide is similar to that described for the chemically related salicylanilide closantel.

Following oral dosing, rafoxanide is absorbed from the small intestine into the bloodstream. Peak plasma levels occur between 24 and 48 hours. Its bioavailability, measured as AUC and C_{max}, was 2.5 to 3-fold greater in 5 to 8-week-old suckling lambs compared to weaned lambs aged 21–22 weeks (Swan and Mülders, 1993). Rafoxanide is extensively bound (>99%) to plasma proteins and has a long (16.6 days) terminal half-life. The blood is the primary source for the uptake of rafoxanide via the digestive system of the hematophagous helminths. Also, the efficacy of rafoxanide against immature liver flukes is due to its prolonged persistence in the plasma, with subsequent effects on maturing flukes as they reach the bile ducts. In addition, liver fluke infection did not alter the plasma disposition of rafoxanide in sheep (Benchaoui and McKellar, 1993). An injectable solution of ivermectin (1%) plus rafoxanide (12.5%) has been licensed for the treatment of endo- and ectoparasites of cattle, buffaloes, camels, sheep, and goats (El-Banna et al., 2008). This combined formulation is available for SC injection at 2.5 mg/kg of rafoxanide and 200 µg/kg of ivermectin. Enhanced ivermectin AUCs and prolonged elimination half-lives were observed after administration of this combined product to both adult male sheep and calves. Whether or not rafoxanide inhibited the P-glycoprotein-mediated elimination of ivermectin remains to be elucidated.

Rafoxanide is not metabolized to any detectable degree by cattle or sheep liver. Following a single oral dose of 15 mg/kg in cattle, no residue of the compound is detectable in edible tissues at 28 days after treatment. Interestingly, approximately a 20% loss of rafoxanide residues was observed in both fried and roast cattle beef (Cooper et al., 2011). Rafoxanide is not allowed for treating animals whose milk is intended for human consumption. Neither pasteurization nor manufacturing processes for production of skim-milk powder affected the stability of rafoxanide residues (Power et al., 2013). Moreover, rafoxanide residues were between 10- and 14-fold higher in skim-milk powder, butter, and cheese than in the starting milk.

Oxyclozanide

Oxyclozanide (3,3′,5,5′,6-pentachloro-2′-hydroxy salicylanilide) (Figure 40.9) was introduced over 40 years ago for use against adult fluke infections in ruminants. It has been also used against tapeworms (*Moniezia* spp.) in sheep and cattle. This anthelmintic is marketed as an oral drench (aqueous suspension) containing oxyclozanide only or in combination with levamisole hydrochloride or oxfendazole. It is also formulated as a powder to be incorporated in the feed. The recommended dose rates are 10–15 mg/kg for cattle and 15 mg/kg for sheep and goats. The mechanism of action of oxyclozanide is similar to that described for closantel. Following its oral administration to sheep, the drug is extensively (greater than 99%) bound to plasma proteins and the plasma concentration/time curve could be best described by a triexponential equation. Its terminal half-life (6.4 days) is shorter compared with closantel and rafoxanide (14.5 and 16.6 days, respectively) (Ali and Bogan, 1987). The drug is excreted into the bile as a glucuronide metabolite. Figure 40.11 shows the comparative plasma profiles and some kinetic parameters for closantel, rafoxanide, and oxyclozanide following their respective oral administrations to sheep.

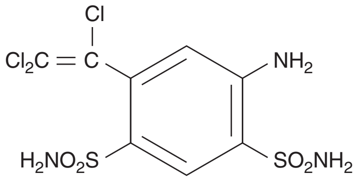
Benzenesulfonamides

Clorsulon

This anthelmintic is a benzenesulfonamide with the chemical formula 4-amino-6-trichloroethenyl-1,3-benzenedisulfonamide (Figure 40.12). Clorsulon is highly effective against adult liver flukes in sheep and cattle. However, is more effective in cattle than in sheep and goats. The recommended dose rate is 2 mg/kg body weight given by SC injection. Good efficacy against 8-week-old flukes is achieved following SC administration at 4–8 mg/kg. Oral administration at 3.75 mg/kg is effective for the treatment of adult liver flukes aged 14–16 weeks in both sheep and cattle. The recommended oral dose rate is 7 mg/kg, which is 100% effective for the treatment of 8-week-old flukes. The same dose rate is 99% effective for the treatment of adult specimens (14 weeks postinfection) in goats. The efficacy of clorsulon has been tested against infections with several other fluke species in ruminants. It was effective (>92%) against immature (8-week-old) *Fascioloides magna* in cattle and sheep at 21 mg/kg orally.



Clorsulon

Figure 40.12 Chemical structure of clorsulon, a bencenesulfonamide flukicidal compound.

Daily dosing at 7 mg/kg for 5 consecutive days has been 100% effective against adult and 92% effective against immature *Fasciola gigantica* in cattle. Clorsulon has poor efficacy against *Paramphistomum* spp.

The combination of clorsulon with ivermectin in a SC injectable formulation was designed for simultaneous treatment of *F. hepatica* and nematode infections of cattle. The oral formulation of clorsulon also can be used concurrently with other anthelmintics (e.g., ivermectin, fenbendazole) with no reduction in efficacy of the individual products. An injectable combined flukicidal and nematodicidal formulation containing nitroxynil, clorsulon, and ivermectin was shown to be highly effective against 2 and 4-week-old early immature flukes (Hutchinson et al., 2009).

Chemically, clorsulon is similar to 1,3 diphosphoglycerate, an intermediary product of glycolysis. Consequently, this anthelmintic was shown to inhibit competitively the enzymes phosphoglycerate kinase and phosphoglyceromutase (Schulman and Valentino, 1982). However, such disruption of glycolysis was observed *in vitro* with clorsulon concentrations many times greater than blood levels achieved *in vivo*. Thus, it is believed that clorsulon effects on the glycolytic pathway at therapeutic concentrations attained in vivo may not be relevant. Nevertheless, glycolysis is the main energy yielding pathway in the fluke and any disruption of this process would decrease glucose utilization and the production of metabolic end products (acetate and propionate) with a significant reduction in ATP levels within the parasite. Morphological changes in fluke specimens recovered from clorsulon-treated rats include severe necrosis of the gastrodermal cells and tegumental damage restricted to the cone and midbody regions of the fluke (Fairweather and Boray, 1999; Meaney et al., 2003, 2004). It has also been shown that the gut was more severely affected than the tegument, which is consistent with the observation that oral ingestion is a main route of entry of clorsulon into the fluke (Meaney et al., 2005). Thus, the changes in the gut represent the direct consequence of drug action, while those observed in the tegument represent either the direct effect of transtegumental uptake of clorsulon from the bile or an indirect effect derived from gut disruption. Clorsulon in combination with triclabendazole caused a greater disruption of the fluke's tegument compared to the individual drugs (Meaney et al., 2005). This effect was observed in vitro and in vivo when the combination was used against a triclabendazole-resistant strain of *Fasciola hepatica*.

Clorsulon is marketed as an oral drench for sheep and cattle and as an injectable formulation (in combination with ivermectin) for SC administration to cattle. The recommended dosage of clorsulon for cattle and sheep is 7 mg/kg by oral drench. In commercial combination with ivermectin, clorsulon is administered SC to cattle at a rate of 2 mg/kg and ivermectin at 0.2 mg/kg. The oral drench is an aqueous suspension containing 8.5 mg/ml of clorsulon dissolved in propylene glycol/water (1/10). The pharmacokinetic behavior of clorsulon was studied in sheep and goats after administration of a single IV and after a single oral dose of 7 mg/kg (Sundlof and Whitlock, 1992). These authors reported that the bioavailability of orally administered clorsulon was approximately 55% in goats and 60% in sheep. Peak plasma concentrations occurred at 14 hours and 15 hours after oral administration in goats and sheep, respectively. Absorption from the GI tract effectively prolonged the elimination of clorsulon, increasing plasma elimination half-lives (about twofold) and MRTs (approximately three to fourfold) in both sheep and goats. It has been shown that the rumen may substantially influence the absorption pattern and the resultant pharmacokinetic behavior and antiparasite activity of enterally delivered anthelmintic drugs. This fact has been thoroughly studied for benzimidazole anthelmintic drugs. Similarly, when a suspension of clorsulon is deposited in the rumen, the adsorption of its particles to digesta solid content, the slow mixing and long digesta residence time, and the large rumen volume assists absorption by delaying the rate of passage of drug down the GI tract (Hennessy, 1993). Thus, the rumen may act as a reservoir and prolong the duration of drug absorption and/or outflow down the GI tract. Indeed, the absorption pattern of clorsulon from the GI tract influences its pharmacokinetic behavior and, consequently, its elimination from plasma is delayed. In rats, clorsulon was shown to be bound predominately to erythrocytes at doses below 4 mg/kg. In fact, the drug is bound to red blood cell carbonic anhydrase (Schulman et al., 1982). As explained above in this section, this is the major route of entry of clorsulon into the fluke and drug uptake by *F. hepatica* increase in direct proportion to the blood level.

Renal excretion of the parent drug is thought to be the main route of elimination of clorsulon, accounting for approximately 50% of the IV dose at 48 hours in both sheep and goats. On the other hand, up to 30% and 41% of the orally administered dose was recovered in urine in sheep and goats, respectively (Sundlof and Whitlock, 1992). The elimination rate constant (kel) in goats was nearly twice as large as the value determined in sheep, and the AUC following IV administration in goats was only 63% of the value observed in sheep, indicating that goats are more effective in their ability to eliminate clorsulon than are sheep. These differences in drug disposition between sheep and goats may account for the reduced efficacy of clorsulon reported in goats.

Clorsulon is a safe drug with high therapeutic index. Acute toxicity of this antiparasite has been assessed in mice, rats, sheep, and cattle. The LD_{5O} in mice is an intraperitoneal (IP) dose of 761 mg/kg and more than 10,000 mg/kg orally. The latter dose causes no apparent toxicity in rats. Sheep infected with flukes have been dosed repeatedly with 5 mg/kg daily for 28 days or with single doses of 100 mg/kg with no apparent effect. Uninfected sheep tolerated 200 or 400 mg/kg without adverse reactions. A toxic dosage has not been identified in cattle. Oral doses of 7 mg (recommended) and 21 mg/kg on 3 consecutive days and single oral doses of 7, 70, and 175 mg/kg (i.e., up to 25 times the label dosage) have not affected weight gains, feed consumption, or clinical or histopathological parameters adversely. In uninfected goats, experimental dosages up to 35 mg/kg every other day for three doses did not cause adverse reactions. Clorsulon is also considered safe for use in breeding and pregnant animals. Residue studies indicate a short half-life of clorsulon in tissues and milk. Milk taken from treated animals within 72 hours (six milkings) after treatment should not be used for human consumption, and beef animals should not be slaughtered within 8 days of treatment.

Benzimidazoles

The pharmacology of the broad-spectrum benzimidazole (BZD) anthelmintic compounds has been fully described in Chapter 39. Albendazole (used at 7.5 mg/kg in sheep and at 10 mg/kg in cattle) and the pro-BZD netobimin (20 mg/kg) are active against liver flukes older than 12 weeks. Fenbendazole is not effective against *F. hepatica*, but a single treatment at 5 mg/kg reduced *F. gigantica* infection in sheep by up to 95%. Luxabendazole is also an effective flukicidal BZD which did not reach the market. However, the halogenated BZD thiol named triclabendazole, which does not have nematocidal activity, is the most widely used and potent flukicidal drug active against immature and mature stages of *F. hepatica*. Its pharmacological features are described in Section Triclabendazole.

Triclabendazole

Unlike other BZD compounds, the halogenated derivative triclabendazole (5-chloro-6(2-3 dichlorophenoxy)-2-methylthio-1H-benzimidazole) (TCBZ) (Figure 40.13) holds an excellent efficacy against the adult and juvenile stages of *F. hepatica* (down to 1-week-old flukes), which is unlike other available flukicidal drugs (Boray et al., 1983). The high activity of TCBZ against immature flukes is significant because they represent the migratory stage of the parasite, which may produce serious tissue damage in the host. However, TCBZ activity appears to be restricted to *F. hepatica*, *F. gigantica*, *Fascioloides magna*, and the lung fluke, *Paragonimus* spp. (Calvopiña et al., 1988), because the drug does not show clinical efficacy against nematodes, cestodes, and other trematode (*Dicrocoelium dendriticum*, *Paramphistomun* spp., and *Schistosoma mansoni*) parasites.

Figure 40.13 Triclabendazole (TCBZ) and its main metabolites: chemical structures and metabolic pathways. See the text for further explanation on TCBZ metabolism.

The precise mode of action of TCBZ has not yet been established. BZD nematocidal activity is based on its binding to parasite β-tubulin (Lacey, 1988), which inhibits polymerization into microtubules. Thus, all the functions ascribed to microtubules at the cellular level are altered (cell division, maintenance of cell shape, cell motility, cellular secretion, nutrient absorption, and intracellular transport). BZD methylcarbamate molecules such as albendazole or fenbendazole act upon nematode microtubules at the tubulin colchicine binding site (Lacey, 1988). It is likely that a different site of action is involved on the flukicidal activity of TCBZ, which could also explain its lack of efficacy against other helminth parasites. However, there are morphological data that support the possible binding of TCBZ to the fluke's tubulin. The TCBZ sulfoxide metabolite (TCBZSO) blocks the transport of secretory bodies from the cell body to the tegumental surface, culminating in the total loss of the tegument (Stitt and Fairweather, 1994). TCBZSO also inhibits the mitotic division of spermatogenic cells and the stem vitelline cells, all changes related to microtubule inhibition. It is likely that TCBZ/metabolites may target an alternative binding site on the tubulin molecule (Fairweather, 2005).

The pharmacokinetics of TCBZ has been characterized in sheep (Hennessy et al., 1987), goats (Kinabo and Bogan, 1988), and cattle (Sanyal, 1995). TCBZ parent drug is not detectable in plasma after its oral administration to sheep and cattle, TCBZSO and TCBZ-sulfone (TCBZSO$_2$) being the metabolites recovered from the bloodstream of treated animals (see Figure 40.14). These metabolites reach a peak plasma concentration after 18 and 36 hours posttreatment, respectively, in sheep. Furthermore, extremely low concentrations of TCBZ were recovered in bile, TCBZSO, TCBZSO$_2$, and the hydroxy-TCBZ derivatives being the major

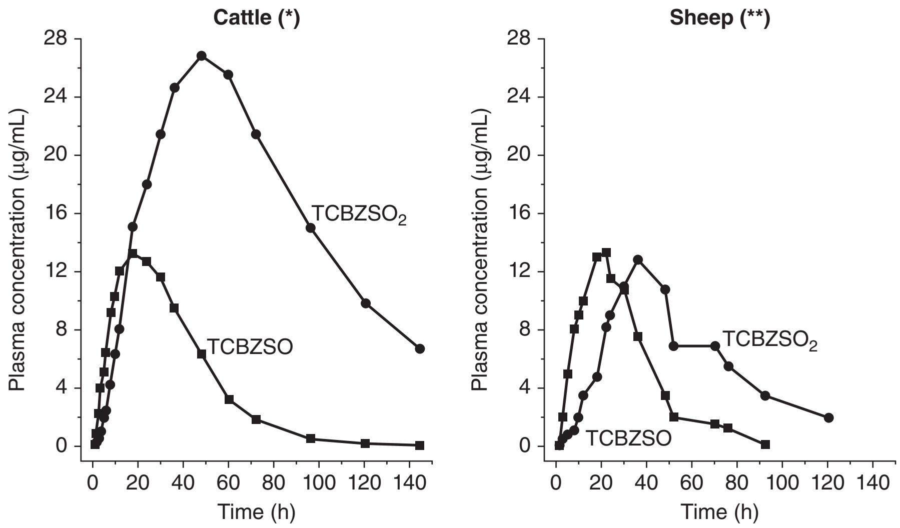

Figure 40.14 Plasma concentration profiles of triclabendazole sulfoxide (TCBZSO) and sulfone (TCBZSO$_2$) obtained after triclabendazole administration to cattle (orally, 12 mg/kg) and sheep (intraruminal, 10 mg/kg). Source: *Data from Lanusse et al., unpublished observations. **Adapted from Hennessy et al., 1987.

biliary metabolites found in sheep (Hennessy et al., 1987) (see Figure 40.13). The metabolic fate of TCBZ and its metabolites was characterized in sheep (Virkel et al., 2006). Both flavin monooxygenase (FMO) and cytochrome P450 enzymatic systems were found to be involved in the sulfoxidation and sulfonation of TCBZ in sheep liver. In addition, sheep ruminal microflora was able to reduce TCBZ sulfoxide derivatives, TCBZSO and hydroxy-TCBZSO, into TCBZ and hydroxy-TCBZ, respectively.

As for other nematocidal BZD sulfoxides, the sulfoxide metabolite of TCBZ is believed to have flukicidal activity. In fact, the tegument of *F. hepatica* is highly susceptible to TCBZSO, since the compound causes severe surface damage after a relatively short exposure time (Stitt and Fairweather, 1994). TCBZ metabolites bind strongly (>99%) to plasma proteins, specifically albumin. The long persistence of TCBZ metabolites in the bloodstream (over 120 hours posttreatment) and their high plasma concentrations compared to other BZD compounds, correlate with their high plasma protein binding. These may contribute to its high flukicidal activity, based on a high and prolonged drug exposure of the blood-feeding adult flukes. On the other hand, the metabolic conversion of TCBZSO into TCBZ in the rumen may give rise to a source of the main active metabolite in the liver (Virkel et al., 2006). Thus, the sulforeduction of hydroxy-TCBZSO into hydroxy-TCBZ may be relevant as well, although the mode of action and/or the anthelmintic activity (if any) of these metabolites have not been established. Approximately 45% of the administered dose is eliminated by bile and only a 6.5% is excreted in urine, mainly as TCBZSO and TCBZSO$_2$ (Hennessy et al., 1987).

Flukicidal drugs can reach target sites within *F. hepatica* either by oral ingestion of blood or by transtegumental diffusion. The large absorptive surface area of the fluke's tegument may have a major role in drug diffusion from the surrounding medium. Studies on ex vivo drug diffusion into TCBZ-susceptible *F. hepatica*, demonstrated that TCBZ, TCBZSO, and TCBZSO$_2$ have the capability to penetrate the fluke's tegument (Alvarez et al., 2004; Mottier et al., 2004). Unlike the uptake pattern previously observed for albendazole (Alvarez et al., 2001), the parent TCBZ and its sulfoxide and sulfone metabolites showed a similar ability to penetrate into the trematode parasite. However, the diffusion of the hydroxy-derivatives into the fluke was lower than that observed for TCBZ, TCBZSO, and TCBZSO$_2$. These findings agree with the high correlation observed between lipophilicity and drug concentrations measured within the parasite. Those studies demonstrated that the higher the lipophilicity, the greater the ability of the BZD molecules to cross through the helminth external surfaces. These studies have also shown that the composition and physicochemical characteristics of the incubation medium drastically affect the diffusion of BZD anthelmintics into *F. hepatica*. The time course and pattern of in vivo accumulation of TCBZ and its metabolites in bile, liver tissue, and *F. hepatica* specimens was studied in sheep treated with TCBZ (10 mg/kg) by the intraruminal route (Moreno et al., 2014). Both TCBZSO and TCBZSO$_2$, the only metabolites detected in the bloodstream, were the main metabolic products accumulated within the adult flukes (see Figure 40.15). This finding confirms that oral ingestion is a main route of entry of TCBZ metabolites in vivo. The administered drug (TCBZ) was the main compound accumulated in the liver tissue, whereas low concentrations of this parent drug were recovered from collected parasites. The presence of TCBZ within adult fluke specimens (despite being absent in the bloodstream) may indicate some degree of transtegumental diffusion from bile/liver tissue of treated animals.

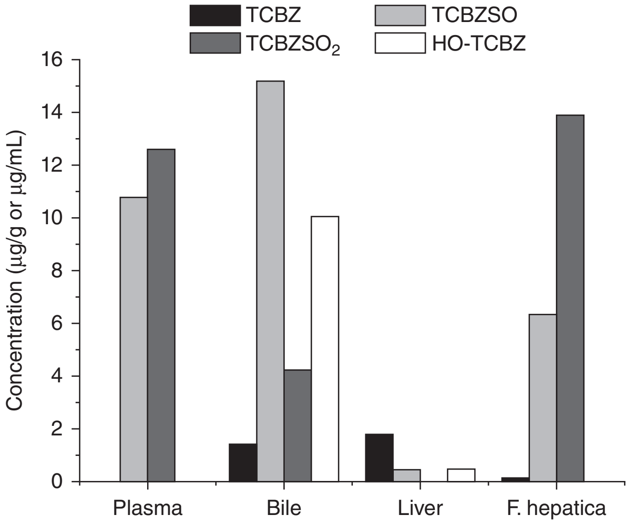

Figure 40.15 Triclabendazole (TCBZ), triclabendazole sulfoxide (TCBZSO), triclabendazole sulfone ($TCBZSO_2$) and hydroxy triclabendazole (HO-TCBZ) concentrations (µg/g or µg/ml) measured in plasma, bile, adult *Fasciola hepatica* and liver tissue at 24 h post-administration of TCBZ (intraruminal at 10 mg/kg) to sheep. See the text for further explanation. Source: Adapted from Moreno et al., 2014. Reproduced with permission of Elsevier.

Since TCBZ is the most widely used flukicide, due to its excellent activity against both the mature and immature stages of *F. hepatica,* the selection of TCBZ-resistant populations is now an emerging problem in several areas of the world (Fairweather, 2005). BZD resistance in *H. contortus* has been associated with the loss of high-affinity binding (Lubega and Prichard, 1991) and an alteration of the β-tubulin isoform pattern. Although the flukicidal activity of TCBZ remains to be fully understood, there are data to support a microtubule-based action of this compound (Stitt and Fairweather, 1994). However, it has been shown that the TCBZ-resistant phenotype in *F. hepatica* is not associated with residue changes in the primary amino acid sequence in β-tubulin (Robinson et al., 2002). This suggests that there may be an alternative mechanism of TCBZ resistance. In fact, the amount of TCBZ recovered from resistant flukes was significantly lower (~50%) than that measured in susceptible parasites. Increased TCBZ oxidative metabolism by the fluke and enhanced drug efflux mediated by ATP-dependent transmembrane transporters may account for the reduced drug accumulation observed in resistant flukes (Alvarez et al., 2005; Mottier et al., 2006), and have been proposed as potential mechanisms of TCBZ resistance in *F. hepatica*. In this regard, *in vitro* studies showed a greater disruption of tegumental, vitellogenic, and spermatogenic cells when TCBZ-resistant specimens of *Fasciola hepatica* were exposed to a combination of TCBZSO and the known P-glycoprotein inhibitor verapamil (Savage et al., 2013, 2014). Conversely, albendazole accumulation was similar in both susceptible and resistant flukes, which correlated with the observed high efficacy of this drug against TCBZ-resistant flukes in the field (Coles and Stafford, 2001) (Figure 40.16)

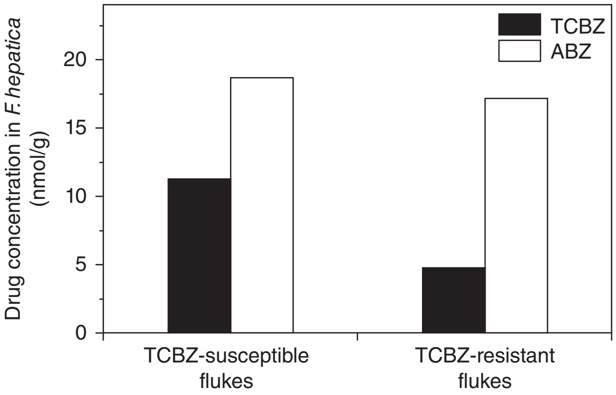

Figure 40.16 Comparative diffusion of triclabendazole (TCBZ) and albendazole (ABZ) into adult specimens of TCBZ-susceptible and TCBZ–resistant *F. hepatica*. See the text for further explanation. Source: Adapted from Mottier et al., 2006. Reproduced with permission of Elsevier.

TCBZ is administered orally to cattle (12 mg/kg), sheep (10 mg/kg), and goats (15 mg/kg), and is indicated for the treatment and control of all stages of TCBZ susceptible *F. hepatica* from 2-day-old early immature to mature fluke, and so is indicated against both acute and chronic fasciolosis. Combined formulations containing TCBZ and different antinematodal drugs (levamisole, abamectin, ivermectin) are available in different countries. The pharmacokinetic properties of both TCBZ and ivermectin coadministered in sheep were evaluated (Lifschitz et al., 2009). Ivermectin elimination was delayed and its plasma availability was threefold higher when given in combination with TCBZ. Similarly, plasma concentrations of TCBZ and its metabolites were influenced by its coadministration with ivermectin. Higher peak plasma concentrations of TCBZ metabolites were observed after the coadministration of TCBZ and ivermectin compared to those obtained following TCBZ alone treatment. It was suggested that TCBZ may modulate ivermectin biliary and/or intestinal P-glycoprotein-mediated elimination. The same rationale was applied for the observed modifications on the systemic exposure of TCBZ and its active metabolite TCBZSO because both molecules were shown to interact with P-glycoprotein (Dupuy et al., 2010).

TCBZ can be administered at any stage of pregnancy. A withdrawal time of 56 days (meat) has been established for TCBZ in sheep and cattle. TCBZ is not indicated to be used in lactating animals producing milk for human consumption, or in pregnant animals that are intended to produce milk for human consumption within 2 months

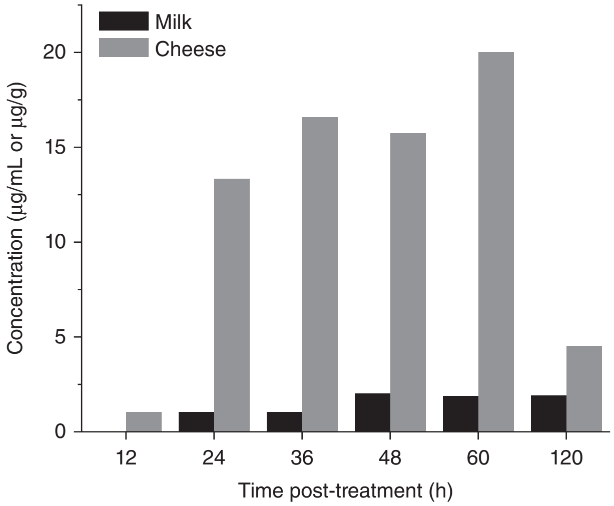

Figure 40.17 Comparison of the total residue levels (sum of triclabendazole sulfoxide and triclabendazole sulfone concentrations) measured in pooled milk and cheese elaborated with milk collected from treated cows at each time interval. Source: Adapted from Imperiale et al., 2011. Reproduced with permission of Taylor & Francis. Food Additives and Contaminants, 28(4):438-445.

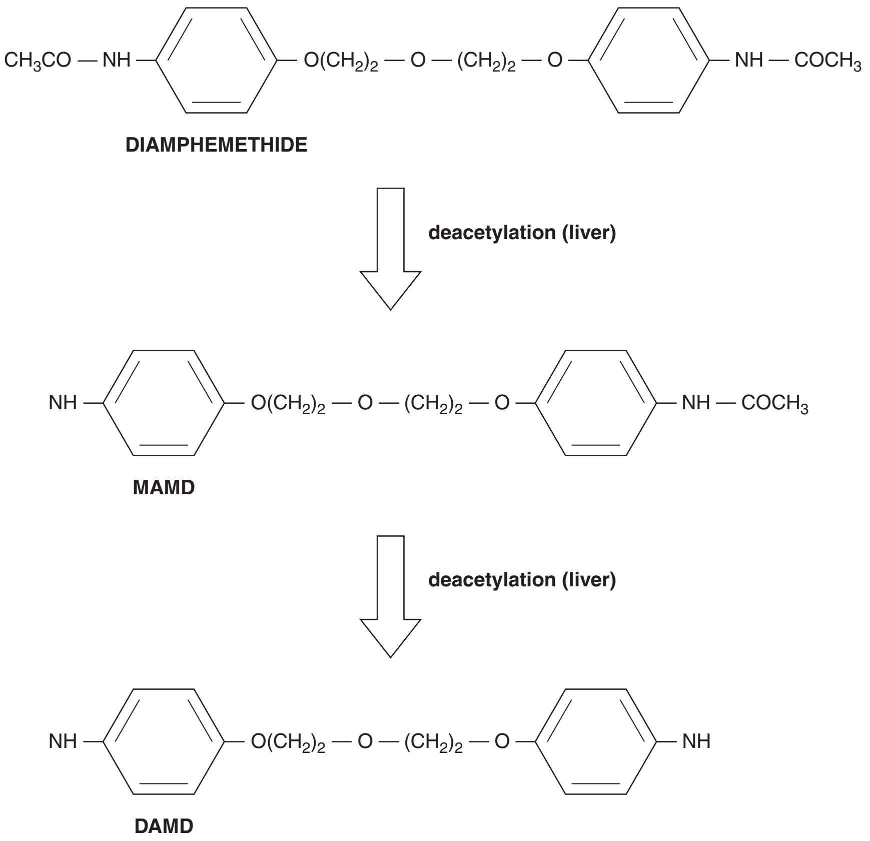
of expected parturition. Both TCBZSO and $TCBZSO_2$ were detected in milk from lactating dairy cattle (up to 36 and 144 hours, respectively) when TCBZ was administered at 12 mg/kg by the oral route (Imperiale et al., 2011). The total average residual concentration in fresh cheese was 13-fold higher than that obtained in milk used for its elaboration (see Figure 40.17). These results reaffirm why TCBZ is banned for use in lactating animals.

Phenoxyalkanes

Diamphenethide

This flukicidal molecule is a phenoxyalkane (*N,N′*-[oxybis(2,1-ethanediyloxy-4,1-phenylene)] bisacetamide) (Figure 40.18). Diamphenetide is exceptionally effective against early immature flukes from 1 day to 6 weeks of age. Consequently, it is used for treatment of acute fasciolosis resulting from immature forms of *F. hepatica* migrating through the liver parenchyma of sheep. A dosage of 100 mg/kg is almost 100% effective against flukes from 1 to 63 days of age. However, its activity progressively decreases as the flukes develop to maturity. This is in direct contrast to other currently used fasciolicides, which tend to be less active against younger flukes. This phenomenon is a drawback for the clinical use of diamphenethide but the drug may be useful in prophylactic programs against liver fluke disease in sheep. A chemoprophylactic effect has been achieved as a result of strategic treatments with diamphenetide in both sheep and cattle (Enzie et al., 1980). At a dosage of 10 mg/kg of body weight (10% of the recommended dose), the drug

Figure 40.18 Diamphenetide: chemical structure and metabolic fate. Liver deacetylation of the parent drug renders into two active diamino metabolites: monoaminodiamphenethide (MAMD) and diaminodiamphenethide (DAMD).



resulted 87% effective in preventing establishment of *F. hepatica* infections in sheep that were given the drug daily for 14 days, and was 96% effective in sheep that were given the drug for 21 days (Enzie et al., 1980). It has also been proposed the use of a controlled-release device of diamphenethide for the prophylaxis of fasciolosis in ruminants (Rew and Knight, 1980).

The efficacy of diamphenethide depends upon deacetylation of the drug by liver enzymes (deacetylases) to an amine metabolite. Diamphenethide is not active in vitro, but its deacetylated (amine) metabolite (DAMD) has flukicidal activity against liver flukes. The exact mechanism of action of DAMD remains not well established as yet. Although it was shown that DAMD caused severe morphological damage to *F. hepatica* in vitro, energy metabolism is not the prime target for this metabolite (Fairweather and Boray, 1999). DAMD-induced disruption of the tegument and osmoregulatory system of the fluke was thoroughly described using transmission electron microscopy (Anderson and Fairweather, 1995). Morphological changes include swelling of the in-foldings of the basal plasma membrane leading to flooding of the syncytium and eventual sloughing of the tegument. Further information on the mode of action of DAMD can be obtained from Fairweather and Boray (1999).

Diamphenethide is administered as an oral suspension at 100 mg/kg in sheep and goats. Diamphenethide is absorbed into the blood after oral treatment and readily metabolized in the liver. High concentrations of two active deacetylated metabolites, monoamino- (MAMD) and diamino-diamphenethide (DAMD) are produced in liver parenchyma, where immature flukes are found until at least 7 weeks after infection. Metabolites reach high concentrations in the liver parenchyma but are thought to be rapidly biotransformed and eliminated into the bile. Only small amounts of MAMD and DAMD may escape into the bloodstream but become diluted. This is why the quantity of active metabolites reaching mature blood-sucking flukes by both oral ingestion or tegumental diffusion is small. Therefore, efficacy against adult stages located in the bile ducts is reduced.

Safety of diamphenetide for the host can be explained on the basis of destruction of the metabolites by the liver and dilution in blood so that only small quantities reach other tissues. Its greatest concentrations are measured in the liver and gallbladder content (at 3 days posttreatment). It should be noted that adult flukes reside in intimate association with the biliary system. At 7 days after dosing, concentrations of diamphenethide in these sites are reduced approximately 10-fold, to a range of only 0.1–0.5 ppm, while concentrations in the musculature are approximately 0.02 ppm. In the United Kingdom, animals intended for human consumption are permitted to be slaughtered 7 days after treatment. The usual oral dose (100 mg/kg) in sheep is apparently safe. A single oral dose four times the therapeutic dosage (400 mg/kg) produces no toxic signs. At higher dosages, toxic effects include temporary impairment of vision and loss of wool. Pastured sheep are less susceptible to toxic effects than housed sheep. There appear to be no significant contraindications for use of diamphenethide. Pregnant ewes dosed with 200 mg/kg once weekly on 2, 3, or 4 consecutive occasions during the 21-week gestation period exhibited no adverse effects on fertility or teratogenic effects in their offspring.

Macrocyclic Lactones: Endectocide Compounds

Carlos E. Lanusse, Fernanda A. Imperiale, and Adrian L. Lifschitz

General Pharmacology: Avermectins and Milbemycins

The integration of available information on the host–parasite–environment relationship with a more complete understanding of the pharmacological properties of existing antiparasitic drugs should result in more efficient parasite control in domestic animals. The time of parasite exposure to active drug concentrations determines the efficacy and/or persistence of activity for the most of the anthelmintic drugs used in veterinary medicine. The characterization of drug concentration profiles in tissues of parasite location and within target parasites provides a basis for understanding the differences in therapeutic and preventive efficacies observed for the different anthelmintic chemical families.

The avermectins and milbemycins are closely related 16-membered macrocyclic lactones (MLs), produced through fermentation by soil dwelling actinomycetes (*Streptomyces*). It was the unique combination killing of endo- and ectoparasites that gave rise to the embracing name *endectocide* by which the MLs are recognized (Shoop et al., 1995a). Information on the antiparasitic properties of the different ML compounds in all animal species has been thoroughly reviewed elsewhere (Campbell, 1985; Shoop et al., 1995a; McKellar and Benchaoui, 1996). Specific literature devoted to the MLs (Vercruysse and Rew, 2002; Gonzalez-Canga, 2012), is recommended for readers interested on any further detailed issue within the topic. Enormous progress on understanding the relationship among disposition kinetics, tissue distribution, and the patterns of antiparasitic persistence for the ML molecules has been achieved, particularly in ruminant species. The purpose of this chapter is to provide an updated and integrated overview of the main basic pharmacological features of the ML compounds, which account for their outstanding long-persistent broad-spectrum antiparasitic activity. The MLs are now considered the most widely used broad-spectrum antiparasitic drugs in veterinary medicine. Chapter 43 describe MLs use as ectoparasiticides.

Avermectins are produced as a mixture of different components from fermentation of *Streptomyces avermitilis*. These natural products are denoted as A (those containing a methoxy group at the 5-position) and B (with a hydroxy group at the 5-position). The highest anthelmintic potency is held by the B1 homologs. The avermectin family includes a series of natural and semisynthetic molecules, such as *abamectin*, *ivermectin*, *doramectin*, *eprinomectin*, and *selamectin*. Abamectin is the naturally occurring avermectin approved for animal use and the starting material for the production of ivermectin. In fact, ivermectin, the first marketed endectocide molecule, is a semisynthetic derivative of the avermectin family. Ivermectin is the generic name given to a mixture of two chemically modified avermectins containing at least 80% of 22-23-dihydroavermectin B1a and less than 20% of 22-23-dihydroavermectin B1b (Fisher and Mrozik, 1989). Doramectin was obtained by mutational biosynthesis in which the precursor (cyclohexanecarboxylic acid) was fed to a mutant strain of *Streptomyces avermitilis* (Goudie et al., 1993). Eprinomectin is a semisynthetic avermectin compound, developed for topical use in cattle (Shoop et al., 1996). Selamectin is a semisynthetic monosaccaride oxime derivative of doramectin more recently introduced into the market for parasite control in dogs and cats (Bishop et al., 2000). The main chemical differences among the avermectin-type compounds are shown in Figure 41.1. It has been shown that minor chemical changes may have a profound impact on the activity of the avermectin analogs. For instance, substitution of the C-5 hydroxy with an oxo-substituent on ivermectin or doramectin monosaccharides can drastically reduce activity against *Haemonchus contortus* larvae.

Nemadectin, *moxidectin*, and *milbemycin oxime* belong to the *milbemycin* family. Milbemycin oxime consists of two oxime derivatives (A_4 and A_3 components) of the 5-didehydromilbemycin in an 80 : 20 ratio. Moxidectin is a milbemycin compound produced by a combination of fermentation and chemical synthesis. Moxidectin is obtained by chemical modification of

Figure 41.1 Chemical structures of the main avermectin compounds used in veterinary medicine. The main chemical differences between abamectin (the natural fermentation product) and other avermectin-type molecules are shown. The commercially available preparations of abamectin and ivermectin contain at least 80% of the avermectin B_{1a} (the a-component has a secondary butyl side chain at the 25-position) and no more than 20% of avermectin B_{1b} (the b-component has an isopropyl substituent at the 25-position). Eprinomectin contains at least 90% of the B_{1a} and no more than 10% of the B_{1b} component.

Figure 41.2 Comparison between avermectin (ivermectin) and milbemycin (moxidectin) molecular structures. The main pharmacological features shared by compounds in both families are listed. The main chemical differences between ivermectin and moxidectin are at the 13-, 23-, and 25-positions (see text for further explanation).

nemadectin, the natural compound produced when *Streptomyces cyaneogriseus* is grown under controlled culture conditions (Takiguchi et al., 1980). The molecular structures of the two endectocide families are superimposable (Shoop et al., 1995a); however, milbemycins do not have the C_{13} disaccharide substituent in the macrolide ring (Figure 41.2). Additionally, moxidectin differs from ivermectin at the 23-position, where it possess a metoxime moiety. Moxidectin also has a differential substituted olefinic side chain at the 25-position. In spite of these chemical differences, both families share some structural and physicochemical properties, and their broad-spectrum antiparasitic activity against nematodes and arthropods at extremely low dosage rates (Figure 41.2).

Various compounds from both families are used in livestock, companion animals, wildlife species, and humans (ivermectin). Abamectin, ivermectin, doramectin, and moxidectin, currently marketed as injectable, pour-on (cattle), and oral (sheep, goats) formulations, are the most commonly used MLs worldwide to control endo- and ectoparasites in livestock. Exceptional potency, high lipophilicity, and the prolonged persistence of their potent broad-spectrum activity are distinctive features among antiparasitic drugs.

Mechanism of Action: Ecto–Endoparasiticadal Activity

The broad-spectrum ecto–endoparasitic activity of the ML from both families includes selective toxic effects on insects, acarines, and nematodes. However, they do not possess efficacy against cestode and trematode parasites. The MLs induce reduction in motor activity and paralysis in both arthropods and nematodes. The paralytic effects are mediated through GABA and/or glutamate-gated chloride channels (GluCl), collectively known as ligand-gated chloride channels. MLs may act on both receptors and a putative GABA-receptor subunit has been localized along the ventral nerve cord and several neurons in the head of *H. contortus* (Blackhall et al., 2003). However, considerably higher ML concentrations are required for the GABA-mediated effects than for those on the GluCl channels. In fact, a high affinity binding to GluCl channels, producing a slow and irreversible increase in

chloride membrane conductance (Forrester et al., 2003), hyperpolarization, and flaccid paralysis of the invertebrate somatic muscles is now proposed as a main mode of action (Martin et al., 2002; Geary, 2005). The ML endectocides cause paralysis and death of both arthropod and nematode parasites due to their paralytic effects on the pharyngeal pump (Geary et al., 1999), which affects nutrients ingestion, and on the parasite somatic musculature limiting its ability to remain at the site of predilection in the host. In addition, inhibitory effects of the MLs on the female reproductive system may explain the observed reductions in parasite egg production (Fellowes et al., 2000). In *H. contortus*, the pharynx appears to be the most sensitive of the affected muscles (Sheriff et al., 2005). A schematic representation of the proposed main mode of action for the ML endectocides is shown in Figure 41.3.

The GluCl channels are members of the ligand-gated ion channel superfamily uniquely found in invertebrates. Some channel subunits have now been cloned from different nematode parasites, including the free-living nematode *Caenorhabditis elegans*, *H. contortus,* and *Cooperia* spp. (Forrester et al., 2003; Njue and Prichard, 2004), which has facilitated enormous progress in the understanding of the mode of action and mechanisms of resistance of the MLs. A good correlation between the presence of GluCl on neurons and muscle cells and the electrophysiological effects induced by MLs has been observed (Martin et al., 2002). Although several GluCl channel subunits have been identified, the sensitivity to these drugs seems to be associated with the alfa-subunit of the receptor (Arena et al., 1992; Cully et al., 1994; Njue and Prichard, 2004), which is encoded by different genes indicating that nematode resistance to these compounds may be polygenic.

The different ML compounds exhibit a similar, but not identical, spectrum of activity against arthropod and nematode parasites and also show differences on the persistence of their antiparasitic activity. Even though compounds in both the avermectin and milbemycin families appear to have the same mode of action, there is now evidence of some subtle pharmacodynamic differences between families, which seems to account for a higher pharmacological potency of moxidectin compared to ivermectin, particularly evident against resistant nematode parasites. These pharmacodynamic differences have been observed at the GluCl channel where moxidectin is 2.5-fold more potent than ivermectin in terms of the required EC_{50} to activate this receptor expressed in *Xenopus* oocytes (reviewed by Prichard et al., 2003). More recently, Hibbs and Gouaux (2011) proposed a model for the ivermectin binding interactions with amino acids at the GluCl channel of *C. elegans*. Considering the structural differences between moxidectin and ivermectin, it is likely that interaction of moxidectin with the target parasite receptor may differ from that of the avermectins (Prichard et al., 2012).

In contrast to mammals, nematodes have multiple genes coding for transporter proteins, which may be essential to protect them from a broad spectrum of toxins (Prichard and Roulet, 2007). The ATP-binding cassette (ABC) transporters are a family that includes different proteins such as P-glycoprotein (P-GP), multidrug resistance proteins (MRPs), and breast cancer resistant protein (BCRP). P-GP acts as an efflux pump for ML compounds, lowering the local drug concentration achieved at the GluCl receptor site of action. Whereas 14 P-GP encoding genes have been identified in the genome of *C. elegans*, sequences of nine P-GPs have been described in *H. contortus* (Williamson and Wolstenholme, 2012). Different P-GPs have been described in other nematodes, such as *O. volvulus* and cyathostomins. As it was demonstrated with mammalian transporters (see Chapter 50 for further discussion), it seems that they play a similar role in modulating MLs uptake and excretion in nematodes, which may modulate the MLs concentrations reaching the target site. Many studies have shown the role of transporter proteins as a potential mechanism of drug resistance in different helminth species, as it was reviewed in detail by Lespine et al. (2011). In vitro and ex vivo studies have provided clear evidence that moxidectin has a lower affinity for P-GP compared to avermectin-type compounds (Lespine et al., 2007; Ballent et al., 2014). This enhanced ivermectin efflux may account for lower active concentrations achieved at the receptor site in comparison to moxidectin. Data demonstrate minor pharmacodynamic differences between ivermectin and moxidectin, which could explain differences in spectrum and potency, and the advantageous pattern of moxidectin efficacy against ivermectin-resistant nematodes of sheep, goats, and cattle.

Pharmacokinetics

Exchange Between Bloodstream and Target Tissues

The clinical efficacy of the MLs is closely related to their pharmacokinetic behavior, that is the time of parasite exposure to active drug concentrations, which is required to obtain optimal and persistent antiparasitic activity. Their antiparasitic spectrum and efficacy pattern are similar; however, each compound has its own dosage limiting species. Differences in physicochemical properties may account for differences in formulation flexibility, kinetic behavior, and in the potency/persistence of their endectocide activity. Thus, even slight modifications to the disposition kinetics or to the pattern of plasma/tissue exchange may notably affect the persistence of their antiparasitic effect.

An enormous effort has been devoted to characterization of the kinetics of the different MLs in different species. The work on the comparative plasma (Lanusse et al., 1997; Toutain et al., 1997) and target tissues (Lifschitz et al., 1999a, 2000; Sallovitz et al., 2003) disposition kinetics of ivermectin, doramectin, and moxidectin in cattle, the disposition of doramectin (Hennessy et al., 2000; Carceles et al., 2001) and moxidectin (Alvinerie et al., 1998a) in sheep and goats, including evidences on their metabolic stability in the digestive tract (Lifschitz et al., 2005) and involvement of lymphatic transport on intestinal absorption (Lespine et al., 2006a), have contributed greatly to the understanding of the overall ML pharmacokinetic properties. Additionally, the characterization of the plasma/milk profiles of eprinomectin in cattle and goats (Shoop et al., 1996; Alvinerie et al., 1999a), the studies on the comparative milk excretion patterns of different ML in dairy sheep, and their impact on drug residue profiles in milk-derived products (Imperiale et al., 2004a), have further contributed to the knowledge on ML kinetic behavior. The main pharmacokinetic features accounting for the persistent broad-spectrum antiparasitic activity of endectocides in ruminants are summarized in Figure 41.4.

Plasma concentration profiles may help to predict the persistence of antiparasitic activity, particularly after parenteral administration. However, the measurement of drug concentration profiles at the site of parasite location and thus antiparasitic activity (the so-called biophase in the pharmacodynamic models of Chapter 4), permits a more direct interpretation and provides a basis for understanding the differences in therapeutic and preventive efficacies observed for MLs. The characterization of drug concentrations at the sites of parasite infection for moxidectin, ivermectin, and doramectin in cattle, and the characterization of the kinetic disposition of doramectin

Drug availability is expressed as area under the concentration vs. time curve (AUC) in ng.day/ml (plasma) and ng.day/g (target tissues). The correlations between drug concentrations measured in plasma and in a target tissue (skin) are shown in the right panel. r, correlation coefficient. Source: Data from Lifschitz et al., 2000.

in fluid and particulate digesta throughout the gastrointestinal tract in sheep, represent a considerable contribution to the understanding of the comparative persistence of activity of these compounds in ruminants. The highly lipophilic MLs are extensively distributed from the bloodstream to different tissues. Their extensive tissue distribution agrees with the high availability of these drugs in different parasite location tissues such as the gastrointestinal mucosal tissues, lungs, and skin in cattle (Figure 41.5), where concentrations markedly greater than those observed in plasma were measured during 50–60 days posttreatment. A strong correlation between plasma and tissue concentration profiles has been observed after the subcutaneous administration of ML compounds. The high correlation coefficients obtained showed the degree of association between ML concentrations in the bloodstream and those measured in tissues of parasites location. Despite the high correlation observed between concentrations in plasma and in tissues/fluids, ivermectin, doramectin, and moxidectin concentrations were greater in all target tissues compared to plasma.

MLs are extremely effective against adult and larval stages of most gastrointestinal nematodes and *Dictyocaulus viviparus* in the lung in cattle, exerting a prolonged protective effect. The achievement of high drug availability in lung tissue may explain their excellent activity against lungworms. The pulmonary tract was the target tissue in which the highest doramectin concentrations were recovered in parenterally treated cattle (Lifschitz et al., 2000). The persistence of the broad-spectrum anthelmintic activity of the MLs against adult and immature gastrointestinal parasites is facilitated by their advantageous pattern of distribution and prolonged residence in the digestive mucosal tissue. Differences in the plasma pharmacokinetic profiles between doramectin and ivermectin have been reported in cattle. Following intravenous administration of an aqueous micelle formulation to determine the intrinsic kinetic features of the compounds, higher plasma concentrations and delayed elimination of doramectin compared to ivermectin were reported (Goudie et al., 1993). After subcutaneous administration of the commercially available formulations to cattle, higher plasma concentrations and extended plasma residence were observed for doramectin compared to ivermectin. The kinetic variables obtained for ivermectin and doramectin in tissues of parasite location are consistent with the described plasma kinetics data. Enhanced availability and prolonged time of residence in target tissues were observed for doramectin compared to ivermectin. The oil based formulation of doramectin, potentially coupled to a slowed metabolic rate based on the presence of the cyclohexyl group at C_{25} (Goudie et al., 1993), may contribute to the higher plasma and target tissues drug availability of doramectin compared to ivermectin.

Moxidectin is the most lipophilic endectocide agent; its high lipophilicity results in a wide tissue distribution (volume of distribution = 13.6 l/kg) and long residence in plasma, which is clearly reflected in the tissue pharmacokinetic results obtained in cattle. Distribution of the drug into adipose tissue accounts for the larger distribution for this compound compared to other antiparasitic drugs. The concentration of moxidectin in fat after

28 days of treatment in cattle has been shown to be 90-fold higher than that detected in plasma (Zulalian et al., 1994). The large tissue distribution of moxidectin in cattle agrees with the high availability of moxidectin in the gastrointestinal mucosal tissues, lungs, and skin, with concentrations ranging between 1 and 2 ng/g at 28 days posttreatment, and with the extended detection of moxidectin concentrations >0.1 ng/g up to 58 days posttreatment in those tissues. The high C_{max} values and total drug availability obtained in tissues where target parasites are located is in agreement with the extensive tissue distribution of moxidectin, and thus may be relevant in terms of antiparasitic activity against internal and external parasites. Long residence times for moxidectin (between 6.8 and 11.3 days) were obtained in the different sites of parasite location, which agrees with the extended residence of moxidectin reported in fat and in the bloodstream (Alvinerie and Galtier, 1997; Lanusse et al., 1997). Moxidectin depletion half-lives in target tissues ranged from 7.73 days (skin) to 11.8 days (intestinal mucosa) (Lifschitz et al., 1999a), which were significantly longer than those determined for ivermectin and doramectin in the same tissues. The deposit of moxidectin in adipose tissue may act as a drug reservoir that contributes to the long persistence of this molecule in the bloodstream and in different tissues of parasite location. The estimated plasma elimination half-lives for different ML compounds in cattle are shown in Figure 41.6. Drug elimination half-life values for the main host tissues where target endo- and ectoparasites are located, are also shown.

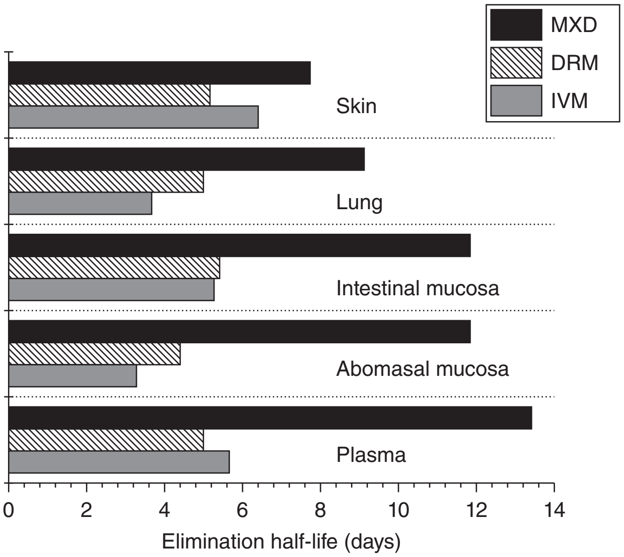

Figure 41.6 Comparative mean elimination half-lives for ivermectin, doramectin, and moxidectin in plasma and tissues of parasite location after their subcutaneous administration to cattle (0.2 mg/kg). Source: Data from Lifschitz et al., 1999a, 2000.

A considerable excretion of ivermectin, moxidectin, and doramectin occurs via mammary glands, which invalidate their use in dairy animals.

However, topical formulations of moxidectin are currently approved for use in dairy cattle in some countries without a milk withdrawal time. Although licking behavior may drastically enhance milk residues of topically administered moxdectin, the residual concentrations reported did not exceed the permitted residual concentrations at any time posttreatment (Imperiale et al., 2009). Topical application is fully discussed in Chapter 43.

In an effort to identify an ML molecule that could be used in dairy cattle, an avermectin-derivative, named eprinomectin, has been developed for topical administration to cattle. While the milk/plasma partitioning for eprinomectin in topically treated cattle falls between 0.1 and 0.2 (Shoop et al., 1996; Alvinerie et al., 1999a), the milk/plasma ratio for ivermectin is between 1 (goats and cattle) (Alvinerie et al., 1993; Alvinerie et al., 1996) and 2 (sheep) (Imperiale et al., 2004b). The high lipid content of the milk may explain the higher rate of ivermectin transfer into sheep's milk. The partitioning of moxidectin into sheep's milk is higher than that of ivermectin with milk/plasma concentration ratios between 10.0 and 18.0 (Imperiale et al., 2004a, 2004b). This is consistent with the higher lipophilicity of moxidectin compared with ivermectin.

Eprinomectin, in addition to its antiparasitic potency and broad spectrum, has a substantially reduced distribution to milk, compared to other MLs, which is probably based in some minor changes introduced to its chemical structure. In fact, changes to the milk partitioning coefficients in lactating dairy animals were achieved by manipulation of the avermectin molecule. The C4″-epi-amino analogues unsaturated at $C_{22\text{-}23}$ showing the lowest distribution into milk was eprinomectin, 4″-epi-acetylamino-4″-deoxyavermectin B_1 (see Figure 41.1), and was the best performing compound in terms of broad-spectrum antiparasitic activity.

Hepatic Metabolism: Bile and Intestinal Excretion

Although some metabolic products have been recovered in plasma after administration of different MLs to cattle, these molecules are minimally metabolized in sheep and cattle, with bile and feces the major routes of excretion for unchanged parent drugs. The major liver metabolite of ivermectin in cattle is a 24-hydroxymethyl-dihydroavermectin B_{1a} derivative (Chiu et al., 1987), identical to that produced by steer and rat microsomes in vitro (Miwa et al., 1982). Similarly, a doramectin metabolite, accounting for 5.75% of the total recovered parent drug, was detected in plasma between 8 hours and 45 days postadministration of doramectin. The metabolism of moxidectin has been shown to produce the C_{29-30} and the C_{14} monohydroxymetyl derivatives as the main metabolic products. These and other hydroxylated metabolites have been recovered from different tissues of moxidectin-treated cattle (Zulalian et al., 1994). More extensive biotransformation of moxidectin, compared to ivermectin and doramectin, would agree with the higher ratio of metabolites/parent drug recovered in plasma of moxidectin-treated animals. Interestingly, while 90% of the fat residue at 21 days posttreatment is moxidectin parent drug, ivermectin parent compound accounts only for an 18% of the total fat residue at the same time posttreatment in cattle.

The avermectins are excreted in high concentration in bile and feces of treated cattle. Following an intraruminally administered dose of doramectin in sheep, 25% is secreted in bile, with 20% of biliary metabolites enterohepatically recycled (Hennessy et al., 2000). Consistently, high concentrations of unchanged moxidectin are excreted by bile and feces (Zulalian et al., 1994), with concentrations greater than 2 ng/ml (ng/g) recovered both in bile and feces up to 48 days posttreatment in cattle (Lifschitz et al., 1999a). As pointed out by Hennessy (2000), the extent to which the biliary-secreted drug and metabolites are presented to the gut lumen, reabsorbed as free compound, and subsequently participate in enterohepatic cycling is a major contributor to parasite exposure. See Chapter 2 for an introduction to this process.

The MLs abamectin, ivermectin, and moxidectin (Pouliot et al., 1997; Dupuy et al., 2001), among many other substances, have been shown to be substrates of the P-GP transport protein. In the mammalian host, P-GP participates in the mechanism of active biliary and intestinal secretion of different molecules from the bloodstream to the gastrointestinal tract. The transepithelial intestinal secretion plays a major role in the elimination of ivermectin in the rat (Laffont et al., 2002). Ivermectin clearance from the small intestine accounted for 27% of the total drug clearance, while bile secretion accounted for only 5% of the total clearance in the rat.

Pharmacokinetic–Pharmacodynamic Relationship

The MLs induce a paralytic effect on the pharynx and somatic musculature of nematodes. Different in vitro assays have been used to evaluate ML effects on nematodes. The migration inhibition assay (LMIA) can be used to detect effects on somatic muscle and related neuromuscular sites. On the other hand, the larval development assay (LDA) is not specific for a particular organ and may involve pharyngeal and/or somatic muscle (Demeler et al., 2013a). A different potency among MLs has been shown with the LDA. Abamectin and moxidectin were the most potent compounds against susceptible and resistant *H. contortus* and *H. placei* strains (Kotze et al., 2014). Ivermectin concentrations of 1 nM paralyze the pharynx of *H. contortus* (Geary et al., 1993) and inhibit larval development of trichotrongyloid nematodes (Gill and Lacey, 1998), while much higher concentrations of ivermectin are needed to obtain an inhibitory effect of larval motility (Gill et al., 1991). Considering that 1 nM of ivermectin equals 0.87 ng/g, it may be possible to establish a correlation between the concentrations used in these in vitro assays with those obtained in target tissues after in vivo treatment. Therefore, it could be assumed that the period of time during which drug concentrations are above 1 ng/g in target tissues would be indicative of the period during which a paralytic effect on nematode pharyngeal pump occurs. The ML concentrations required at the site of parasite location to inhibit parasite establishment or development have not been determined. However**,** it has been theoretically assumed that the period of time during which drug concentrations are above 1 ng/g (the ivermectin concentration equivalent to that required to paralyze the pharynx of *H. contortus* in different in vitro pharmacodynamic assays) in target tissues, would be indicative of the period during which the in vivo anthelmintic activity may persist. While ivermectin concentrations were >1 ng/g in gastrointestinal mucosal tissue and lung tissue for 18 days posttreatment, doramectin and moxidectin profiles remained above that level for 38 days postadministration (Lifschitz et al., 2000). The comparison between these time periods and those obtained in different persistence efficacy trials is interesting. The increases of fecal eggs counts after ivermectin and doramectin administration to cattle indicate that reinfection begins 2–3 weeks and 3–4 weeks after each treatment, respectively (Ranjan et al., 1997). The characterization of drug concentrations in target tissues is useful to estimate the period of time posttreatment in which the endectocide levels at the site of parasite location remain efficacious.

ML compounds have a broad spectrum of activity against adult and larval forms of many gastrointestinal nematodes in cattle. However, this pattern of efficacy varies among different nematode parasites and *Cooperia* spp. seem to be the dose-limiting nematode parasite for these compounds. While the reason for this differential susceptibility among different nematodes remains unknown, the evaluation of ML concentrations in different sections of the gastrointestinal tract provided some useful information. High MLs concentrations were detected in both abomasal and small intestinal mucosal tissues up to 48–58 days postsubcutaneous treatment to cattle, which accounted for the large AUC values observed in both target sites. These concentration profiles obtained in the mucosal tissue were greater than those obtained in abomasal and intestinal fluids. Only low MLs concentrations (below 1 ng/ml) were found in abomasal fluid following its subcutaneous administration to cattle, which is in agreement with the data previously reported for ivermectin (Bogan and McKellar, 1988), where the drug was not detected in abomasal fluid, even when administered at 10 times the therapeutic dose in sheep. The greater MLs concentrations observed in the small intestinal fluid collected distal of the bile duct, compared with the abomasal fluid, may be associated to the biliary excretion of the drug. The higher lipid composition of the gastrointestinal mucosa compared to the fluids, considered to be a more polar medium, may account for the greater moxidectin availability found in the mucosal tissues. The high availability and extended residence of MLs in the abomasal and intestinal mucosal tissues agree with the reported persistence of the anthelmintic effects of the drug against different nematodes.

After oral administration of MLs to sheep, high drug concentrations were measured at the GI tissues of parasite location (abomasum and small intestine) during 3–4 days posttreatment. These concentration profiles were significantly higher than those measured in the bloodstream. The highest drug levels were measured at the abomasal and intestinal contents. These high concentrations in the GI contents are significantly higher than those obtained when the MLs were administered by the subcutaneous route to cattle (Lifschitz et al., 1999a, 2000). The drug concentrations measured in the abomasal content for the MLs reflects the amount of drug accumulated within the adult *H. contortus*. After the administration of MLs by an enteral route (oral, intraruminal), the access of drug to *H. contortus* was substantially greater than that obtained following subcutaneous administration. This finding may confirm that an advantageous transcuticular pattern of drug uptake may occur for nematodes located at the GI tract, when lipophilic compounds formulated as a drug solution are orally administered, achieving large availability of soluble drug at the GI lumen (Lloberas et al., 2012, 2013). The comparison of ivermectin and moxidectin concentration profiles achieved in plasma, GI target tissues, and *H. contortus* collected from infected animals (oral treatments) is shown in Figure 41.7.

Although differences in feeding mechanisms and location in the digestive tract among different nematodes should be considered to understand the overall action of the ML endectocides, the persistence of the broad-spectrum anthelmintic activity of the drug against adult and immature gastrointestinal parasites is facilitated by its pattern of distribution and prolonged residence in the gastrointestinal tract. The described pharmacokinetic differences between moxidectin and ivermectin combined with some subtle mechanistic pharmacodynamic differences (see Section Mechanism of Action: Ecto–Endoparasiticadal Activity), are likely to be responsible for the observed differences in potency, spectrum, and expression of resistance seen between both molecules belonging to different ML families. The overall comparison of the pharmacological properties of moxidectin and ivermectin is shown in Figure 41.8.

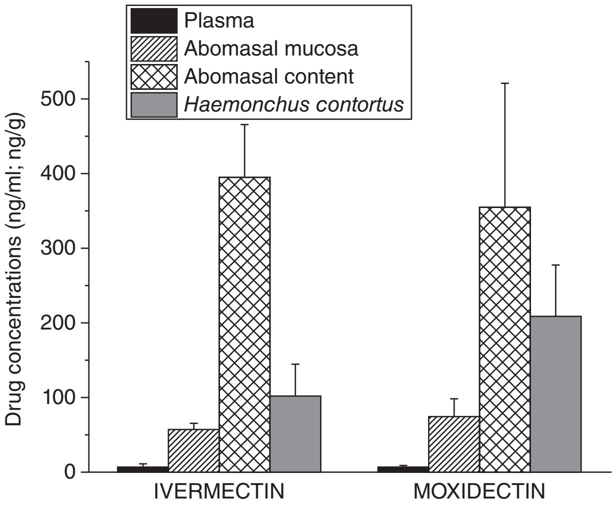

Figure 41.7 Ivermectin and moxidectin concentrations in plasma, gastrointestinal target tissues, and *Haemonchus contortus* measured at 1 day after their intraruminal administration (0.2 mg/kg) to infected sheep. Source: Data from Lifschitz et al., 2013.

ML endectocides are highly effective in eliminating mites and suckling lice species after subcutaneous and topical administration. The pattern of ivermectin and doramectin disposition in skin tissue showed that high concentrations of both molecules (>27 ng/g) are attained during the first 8 days posttreatment (Lifschitz et al., 2000). The sustained presence of high concentrations of ivermectin and doramectin in skin were reflected in prolonged mean residence times (6.8 and 9.3 days, respectively), which may also account for the efficacy of these drugs against single-host ticks. The duration of effective concentrations of endectocide compounds in plasma may be important in the treatment of tick infestations, since this parasite can accumulate lethal drug concentrations through its feeding activity over a period of several days. Drug uptake and efficacy against arthropod ectoparasites can be markedly influenced by parasite feeding habits. Thus, the lower efficacy of the ML against biting lice can be attributed to the lower exposure of this ectoparasite to body fluids containing drug. Moxidectin concentrations greater than 9 ng/g were detected during the first 8 days posttreatment in the skin of treated cattle (Lifschitz et al., 1999a), with a peak concentration of 84.2 ng/g achieved at day 1 postadministration. Drug concentrations in skin declined gradually with time posttreatment, as shown for other tissues, being detectable

up to 58 days (>0.2 ng/g). Interestingly, the ML concentration profiles in the skin (dermis and epidermis) were greater than those found in the hypodermal tissue. Blood vessels in the skin are limited to the dermis, which receives the largest vascular supply. The dermis participates in the exchange of compounds between blood and tissues and as a fat reservoir (Monteiro-Riviere, 1991). The arthropod ectoparasites are exposed to systemic agents during feeding; the nature of their food source, and frequency and duration of feeding can have a marked influence in drug uptake and efficacy (Jackson, 1989).

Therapeutic Uses: Animal Species-Specific Considerations

The ML compounds have exceptional potency and broad spectrum of activity against nematodes and arthropods of different animal species. Their lack of efficacy against trematodes and cestodes may be related to the deficiency of ML-specific binding sites in these parasites (Shoop et al., 1995b). As opposed to benzimidazole anthelmintics, the MLs do not possess ovicidal activity. Compounds from both endectocide families share a similar broad spectrum against endo- and ectoparasites; however, some differences in activity against specific parasites may be observed among different ML molecules. A 0.2 mg/kg dose rate is required for avermectin and milbemycin compounds to eliminate their dose-limiting nematode species such as *Cooperia* spp. and *Nematodirus* spp., and to achieve the full broad-spectrum antiparasitic claim in ruminants (Shoop et al., 1995a). Extensive and detailed information on the spectrum of ecto–endoparasitic activity and on the preventive and therapeutic uses of the ML compounds in different animal species has been thoroughly reviewed elsewhere (Armour et al., 1980; Campbell, 1989; McKellar and Benchaoui, 1996; Vercruysse and Rew, 2002). Readers are also referred to the eighth edition of this text (Reinemeyer and Courtney, 2001) for additional specific information regarding the MLs spectrum of antiparasitic activity. However, some overall concepts on the recommended use of the ML in different animal species are summarized below.

Ruminants

Macrocyclic lactones compounds are available to be administered to ruminants by subcutaneous (cattle, sheep), oral (sheep and goats) (0.2 mg/kg), and topical (cattle) (0.5 mg/kg) formulations. ML are highly effective against immature and adult stages of different gastrointestinal nematode species from ruminants such as *Ostertagia* spp. (including inhibited EL_4 in cattle), *Haemonchus* spp., *Cooperia* spp., *Nematodirus* spp., *Trichostrongylus* spp., *Strongyloides* spp., *Bunostomum* spp., *Trichuris* spp., *Oesophagostomum* spp., and *Chabertia ovina*. MLs also possess high efficacy against lung worms (*Dictyocaulus* spp.) in sheep and cattle. The MLs are active against the most of the nematode parasites affecting goats. However, the low systemic availability of some ML compounds obtained in goats (Scott et al., 1990; Alvinerie et al., 1999b) has restricted their use to extralabel prescriptions given at higher dose rates (0.3–0.4 mg/kg) for both oral and parenteral preparations.

Arthropod parasites controlled by MLs include mites (*Sarcoptes bovis, Psoroptes ovis*), oestrid larvae (*Hypoderma bovis, H. lineatum, Oestrus ovis*), and sucking lice (Linognathus vituli, L. pedalis, and *Hematopinus eurysternus*). Ivermectin, abamectin, and doramectin are highly effective against *Dermatobia hominis* infestations. While ivermectin and abamectin aid in the control of the screw worm *Cochliomya hominivorax*, doramectin has demonstrated a distinctive 100% protection for 21 days postinfection in calves (Moya-Borja et al., 1997). The specific distribution of the MLs in the different skin layers and their prolonged residence agree with its pattern of ectoparasiticide activity. The lower efficacy of the ML subcutaneously administered against biting (*Damalinia spp.*) compared to sucking lice, may be associated with the superficial feeding of these parasites, particularly on sloughed epidermal cells, which may contain low drug concentrations. The pour-on formulations are highly effective to control both sucking and biting lice. MLs are slightly less effective in controlling the sheep ked (*Melophagus ovinus*). MLs are highly efficacious against cattle ticks (*Rhipicephalus microplus*). Ticks are exposed to systemic agents as endectocides during feeding; therefore the frequency and duration of feeding may have a marked influence in drug uptake and efficacy. The ML induces either ticks mortality, lower engorgement, or fewer viable eggs. The injectable ivermectin preparation (1%) shows activity against ticks during 7 days posttreatment. Moxidectin and doramectin provide effective control of ticks for 28 days posttreatment, which is extended up to 75 days in the case of the long-acting 3.15% ivermectin formulations. The ML endectocides contribute to the control of *Haematobia irritans* (horn fly) in cattle. These compounds kill the adult flies and inhibit larval development in cattle dung. Development of the *H. irritans* fly may be reduced over 4 weeks after treatment with some ML compounds in cattle.

The concept of antiparasitic persistence acquired great clinical significance after the discovery and commercial development of the ML endectocide compounds. The intrinsic properties of the ML and/or their pharmacotechnical preparations allow a sustainable persistence of the active drug in the animal body and therefore prevent the establishment of new nematode burdens for several days after treatment. Large variations in the duration of the ML persistence of antiparasitic activity have been reported, particularly in cattle. The high variability is based on the parasites genera involved, the type of formulation used, different host-related factors, and the design of the experimental trials. For instance, the classic 1% ivermectin and abamectin formulations administered subcutaneously to cattle showed a persistent activity against *Cooperia* spp., *Ostertagia* spp., and *Dictyocaulus* spp. during 7, 14, and 28 days posttreatment. Longer protection periods against the same nematode parasites have been reported for moxidectin and doramectin. In fact, doramectin showed a protection period between 21 and 35 days against *O. ostertagi* and 14–28 days for *Cooperia* spp. (Vercruysse et al., 2000). Moxidectin provides a protection against *Ostertagia* spp. and *Dictyocaulus* spp. during 35 and 42 days, respectively (Vercruysse et al., 1997). The ML pour-on formulations protect against nematode reinfection during the same period as that obtained after the subcutaneous treatments in cattle. The available ivermectin sustained-released bolus and the more recently introduced highly concentrated long-acting formulations (ivermectin and moxidectin) recommended for use at higher dose rates (between 0.63 and 1 mg/kg, respectively) dramatically increase the protection periods (between 60 and up to 150 days) against cattle endoparasites.

Swine

The MLs are licensed to be used in pigs by subcutaneous (ivermectin, moxidectin), intramuscular (doramectin) administration at 0.3 mg/kg, and oral feed formulation (ivermectin) at 0.1 mg/kg over 7 days to control endo- and ectoparasites. These compounds are active against immature and adult stages of *Ascaris suum*, *Hyostrongylus rubidus*, *Strongyloides ransomi*, *Oesophagostomum* spp., *Metastrongylus* spp., *Stephanurus dentatus*, and the intestinal (but not muscular) stages of *Trichinella spiralis*. Ivermectin efficacy against *Trichuris suis* is highly variable (between 60 and 95%). The MLs present high activity against the most common ectoparasites affecting swine herds: sucking lice (*H. suis*) and mange mites (*S. scabiei var. suis).*

Horses

Ivermectin (0.2 mg/kg) and moxidectin (0.4 mg/kg) are the only MLs available to be used in horses by either oral paste or gel formulations. Both compounds are highly effective against *Parascaris equorum, Oxyuris equi,* stomach worms *(Draschia megastoma, Habronema* spp.*, Trichostrongylus axei), Strongyloides westeri,* and lungworms *(D. arnfieldi).* Both compounds are effective to control adult and larval stages of large strongyles *(Strongylus vulgaris, S. equinus, S. edentatus),* adult small stronglyles *(Cyathostomes), Gasterophilus nasalis,* and *Onchocerca* spp. *microfilariae.* Consistent with the observed longer residence time in the bloodstream and tissues (Perez et al., 1999), moxidectin shows an extended period of protection against most of the target parasites in horses compared to ivermectin (Demeulenaere et al., 1997). The most important differences in the comparative efficacy of ivermectin and moxidectin in horses have been observed against mucosal larvae of C*yathostomes* and G*asterophilus* larvae. Ivermectin has lower efficacy than moxidectin against encysted *Cyathostomes* (Xiao et al., 1994; Monahan et al., 1996). However, while ivermectin is highly active (>99%) against all instars of *Gasterophilus intestinalis*, moxidectin shows a variable activity that ranges between 20 and 99% of efficacy when administered at recommended doses.

Dogs and Cats

The overall efficacy and safety of the ML designed for other species should not be assumed for dogs. It is now well known that Collie dogs and other dog breeds are particularly sensitivity to ivermectin (see Section Safety and Toxicity). Thus, ivermectin is licensed for specific therapeutic uses in dogs and cats. The available preparations are chewable formulations containing ivermectin to be administered at low doses 0.006 mg/kg (dogs) or 0.024 mg/kg (cats) as preventive against dirofilariasis. Ivermectin is effective against third and fourth stages of *Dirofilaria immitis* (Campbell, 1989). Ivermectin and moxidectin approved formulations have limited-spectrum activity against gastrointestinal nematodes in dogs and cats. However, ivermectin administered orally at higher doses (between 0.05 mg/kg and 0.2 mg/kg) may reach good efficacy against various nematode parasites (*Ancylostoma caninum*, *Trichuris vulpis, Toxocara canis,* and *Capillaria aerophila*). Different studies have shown that two ivermectin subcutaneous doses (0.2 mg/kg) are enough to clear otodectic, sarcoptic, and notoedric mange infestations (Campbell, 1989). Ivermectin is also used in the control of demodectic mange infestations in dogs at higher dosages and prolonged regimens. However, the therapeutic uses of ivermectin in dogs and cats, apart from the prevention of *D. immitis*, should be considered as an extralabel use.

Milbemycin oxime administered at 0.5 mg/kg is effective against developmental stages of *D. immitis, T. canis, T. leonina, A. caninum,* and *T. vulpis*. Moxidectin has been introduced as a tablet (0.003 mg/kg) and long-acting sustained release injectable formulation (0.17 mg/kg) to prevent *D. immitis* infection. This injectable formulation is also useful to control *A. caninum*. Selamectin, a new avermectin compound (see Figure 41.1) introduced as a topical formulation for dogs and cats, is active against different endo- and ectoparasites at 6 mg/kg. A greater selamectin systemic availability was observed in cats compared to that obtained in dogs (Sarasola et al., 2002). It is highly efficacious against infective stages of heartworm (*D. immitis*), *T. canis*, *T. leonina*, *A. tubaeforme,* and *T. cati.* Selamectin is also effective against ectoparasites such as fleas (*Ctenocephalides cati)*, mites (*Otodectes cynotis, S. scabiei*), and ticks (*R. sanguineous* and *Dermacentor variabilis*).

Resistance

The antiparasitic strategies based almost exclusively on chemical control have been threatened by the emergence of nematode parasites resistant to the various anthelmintic chemical classes, including now the ML compounds. The increasing selection pressure on the gastrointestinal nematodes due to the high frequency of ML treatments was relevant for the development of resistance to these compounds. Changes in the glutamate-gated chloride channels structure and an increased expression of different proteins involved in drug efflux (P-GP) have been postulated as the main mechanism of resistance to MLs in nematodes (see Section Mechanism of Action: Ecto–Endoparasiticadal Activity). It has been shown that *H. contortus* resistant to ivermectin has an increased level of P-GP expression and that the coapplication of verapamil (a multidrug resistance (MDR)-reversing agent) increased the efficacy of ivermectin and moxidectin against resistant strains of *H. contortus* (reviewed by Prichard, 2002). The up-regulation of P-GP in *H. contortus* recovered at 1 day postadministration of ivermectin was reported earlier; this also occurs to a lesser degree after the moxidectin administration (Prichard and Roulet, 2007). It has also shown that the ivermectin treatment significantly increased the P-GP2 expression in resistant *H. contortus* recovered from treated lambs 0.5 and 1 days posttreatment compared to worms recovered from untreated animals. The up-regulation of P-GP is in agreement with the highest ivermectin concentrations measured in *H. contortus* (Lloberas et al., 2013). Similar results were obtained in cattle parasites such us *C. oncophora* where the P-GP 11 was up-regulated upon MLs exposure (De Graef et al., 2013).

Initially, resistance to the ML (largely to ivermectin) was observed in sheep and goats nematodes, particularly in *H. contortus*. However, the phenomenon has been widespread and other nematode species from small ruminants have developed resistance to the ML compounds. Field strains of *Teladorsagia circumcincta* and *T. colubriformis* resistant to ivermectin has been identified around the world. In addition, the intensive global use of the different ML compounds over the last 25 years (since the introduction of ivermectin in the early 1980s), has resulted in the emergence of ML resistance in cattle nematodes. Different field strains of *Cooperia* spp., the dose-limiting parasite for MLs, *Trichostrongylus* spp., and Ostertagia spp. have been identified as resistant to the ML compounds (Vermunt et al., 1995; Coles et al., 1998; Fiel et al., 2001; Demeler et al., 2009; Gasbarre et al., 2009; Bartley et al., 2012a). It should be noted that moxidectin conserves activity against some ivermectin-resistant isolates, which is probably due to its differential kinetic and dynamic behavior compared to ivermectin (see Figure 41.8).

A decrease in the selection pressure, reducing the number of treatments per year, together with an integrated antiparasitic control strategy, is urgently required to prolong the usefulness of the broad-spectrum parasite control of MLs in food-animal production. Detailed information on the parasite resistance against ML compounds in ruminant species has been reviewed by Prichard (2002), Wolstenholme et al. (2004), and Wolstenholme and Kaplan (2012).

Despite the widespread resistance of different equine parasites to different anthelmintics, and taking into account that ivermectin has been used in horses for 20 years, there are still no reports of *Cyathostomes* resistance (Kaplan, 2002). ML resistance has been described in *Oxiuris equi* (Wolf et al., 2014) and *Parascaris equi* (Bishop et al., 2014). Considering that ivermectin is the single most commonly used anthelmintic in horses, it seems that emergence of resistance would be inevitable. There are no reports of resistant heartworms, in spite of the fact that MLs have been extensively used to prevent infections in dogs on a monthly basis.

Several reports on ectoparasites resistance to ivermectin have been published. Resistant populations of the cattle tick *Rhipicephalus* (*Boophilus*) *microplus* were identified in Brazil and Mexico (Martins and Furlong, 2001; Klafke et al., 2006; Perez-Cogollo et al., 2010). It seems that some ABC transporters, such as P-GP, may participate as a resistance mechanism to ivermectin in ticks (Pohl et al., 2011).

Pharmacological Interaction with ABC Transporters: Practical Implications

Different in vitro and ex vivo methods have been reported to characterize the interactions between MLs and ABC transporters. It is interesting to note that moxidectin appears to have different P-GP efflux potential, with a half-maximal inhibitory effect (IC_{50}) approximately 10 times higher than that reported for ivermectin (Griffin et al., 2005; Lespine et al., 2007). P-GP may be involved in the ivermectin efflux at low drug concentration, whereas at the higher micromolar concentration range (which may saturate P-GP function), MRP1, and to a lesser extent the MRP2 and MRP3, efflux proteins could participate in ivermectin transport across physiological barriers (Lespine et al., 2006b). The interaction of MLs with BCRP was described (Muenster et al., 2008). It seems that ivermectin is a relatively potent P-GP inhibitor and rather weak BCRP inhibitor. Moxidectin was identified as a BCRP substrate, and the BCRP-mediated secretion of moxidectin in milk was demonstrated using cellular transport assays and pharmacokinetic studies in *BCRP1* (−/−) and wild type mice (Pérez et al., 2009). The involvement of ABC transporters in the milk secretion of MLs may play a relevant role in the clinical use of these compounds in lactating animals due to the presence of residues in milk and derived products.

Important changes to the plasma disposition of the MLs have been observed when these compounds are coadministered with P-GP modulators. The oral coadministration of verapamil with ivermectin induced a significant increase in the ivermectin absorption in sheep (Molento et al., 2004). In lambs the coadministration of quercetin, a derived flavonoid present in vegetables, with moxidectin produced a significant increase on moxidectin plasma concentrations (Dupuy et al., 2003). A significant increment in the systemic availability of ivermectin was obtained after its administration together with the antifungal drugs itraconazole (Ballent et al., 2007) and ketoconazole in sheep (Alvinerie et al., 2008) and dogs (Hugnet et al., 2007). The influence of loperamide (LPM) on the plasma disposition and fecal excretion of moxidectin after intravenous and subcutaneous administration was studied in cattle (Lifschitz et al., 2002b). The modulation of the activity of P-GP has been assayed as a pharmacology-based strategy not only to increase the systemic availability of the MLs in the host animal but also to improve their clinical efficacy. The modulation of P-GP with verapamil, ketoconazole, and pluronic 85 increased the in vitro activity of ivermectin against ivermectin-sensitive and resistant larvae of *T. circumcincta* and *H. contortus* (Bartley et al., 2009). Further scientific support was obtained by demonstrating that verapamil increased the in vitro ivermectin activity against susceptible and resistant isolates of *Cooperia spp.* (Demeler et al., 2013b). Although a modification in MLs activity after P-GP modulation was confirmed in vitro, in vivo trials performed under field conditions are necessary to evaluate the clinical impact of the P-GP inhibition. The enhanced sensitivity of resistant larvae to ivermectin obtained after its coincubation with pluronic 85 did not correlate with their in vivo coadministration to sheep. In the in vivo trial, the presence of pluronic 85 did not improve the efficacy against resistant *H. contortus* (Bartley et al., 2012b). The efficacy of both ivermectin and moxidectin against resistant *Cooperia spp.* in a cattle field trial tended to increase after their coadministration with loperamide, a P-GP modulator (Lifschitz et al., 2010a). This was further corroborated as a significant increase in IVM efficacy against resistant nematodes in sheep together with an enhancement of the systemic availability of the antiparasitic compound in the presence of the P-GP inhibitor (Lifschitz et al., 2010b). Thus, there is evidence that the P-GP-mediated drug–drug interaction increases the ivermectin systemic exposure in the host and it may also decrease the P-GP-mediated efflux transport over-expressed in target resistant nematodes. Table 41.1 summarizes the different in vitro/in vivo assays performed to study the modulation of MLs antiparasitic activity by inhibitors of P-GP. The practical implications of this drug interaction should be carefully investigated regarding the potential side effects induced by the P-GP modulating agents (see Chapter 50 for further discussion). However, the modulation of either P-GP or other proteins involved in

Table 41.1 Influence of P-glycoprotein modulation on the activity/efficacy of different macrocyclic lactones (MLs) against ivermectin susceptible and resistant nematode strains. Source: Adapted from Lifschitz et al., 2012.

ML compound/ P-GP modulator	Parasite/animal species	Modification of activity	Reference
IVM + verapamil MXD + verapamil	*H. contortus* in jirds	Enhanced efficacy (from 1.71 to 2.69-fold)	Molento and Prichard, 1999

drug transport may be a valid pharmacological approach to improve the activity and extend the lifespan of the MLs in veterinary medicine.

Available Pharmaceutical Preparations

Different delivery systems have been developed to administer ML compounds to different animal species. The available preparations include injectable solutions, oral drenches, tablets, pastes, in feed premix, pour-on formulations, and a sustained released bolus (ivermectin). An oral paste containing 1.87% of ivermectin is available for horses. In-feed formulation of ivermectin for pigs is recommended over 7 consecutive days at 0.1 mg/kg per day. Ivermectin is also formulated in a micellar solution for oral drench use in sheep and goats, and as tablet and chewable preparations for oral administration in dogs and cats. The pioneer and worldwide-distributed ivermectin 1% injectable formulation for subcutaneous administration (0.2 mg/kg)in sheep and cattle (Ivomec®, Merial Ltd) is formulated in propylene glycol (60%) and glycerol formal (40%). A topical ivermectin formulation is also commercialized to use against the whole range of ecto- and endoparasites of cattle at 0.5 mg/kg.

Pharmaceutical technology has been applied to develop different drug formulations and delivery systems to optimize the pharmacological potency of ivermectin and other ML endectocides currently available. It has been confirmed that extended residence times of ivermectin in plasma and target tissues and the prolonged persistence of its anthelmintic activity are obtained following the administration of an alternative oil-based formulation to cattle, compared to the standard preparation (Lifschitz et al., 1999b). Recently developed injectable long-acting formulations for cattle are essentially oil based or thixotropic (3.15%) preparations that account for a slow absorption process from the subcutaneous space and a long persistence of active ivermectin concentrations in the bloodstream and target tissues (Lifschitz et al., 1999b, 2007). This 3.15% ivermectin formulation (Ivomec Gold®, Merial Ltd) given at higher dose rates (0.63 mg/kg) has persistent efficacy against cattle gastrointestinal and lung nematodes for up to 77 days and ticks for up to 75 days. Following the same concept of the extended antiparasitic persistence, other similar (generic) highly concentrated (3.15% and 3.50%) ivermectin preparations have been recently introduced into the market for use in cattle in some countries. Another recently developed technology incorporates eprinomectin in a long-acting preparation based on poly (lactic-coglycolic) acid copolymer, which extend its persistent activity against nematodes for up to 120 days (Marley and Tejwani, 2005). The development of sustained-release bolus technology for the administration of antiparasitic drugs was considered an important advance for parasite control. The ivermectin sustained release device is an osmotic bolus delivering

12.7 mg of ivermectin per day over 135 days postadministration to cattle. The excellent release performance of an ivermectin sustained-release bolus was confirmed measuring the plasma and fecal concentration profiles up to 160 days postadministration in cattle; 90% of the total dose released from the bolus was excreted in feces (Alvinerie et al., 1998b).

Controlled-release capsules providing 1.6 mg of ivermectin per day over 100 days have been commercialized for use in sheep. More recently, novel delivery technology has been applied to develop a sequential-release formulation for use in sheep, which delivers ivermectin and albendazole alternately (Gogolewsky et al., 2005). This ivermectin/albendazole sequential delivery (10 days of ivermectin followed by 20 days of albendazole release, with the same alternating release cycle to cover 100 days posttreatment) has been designed to assure the exposure of incoming parasite larvae to two chemicals with different mode of action, which could delay the development of resistance to each of the anthelmintic agents.

Doramectin is available in an oil-based formulation containing sesame oil/ethyl oleate (90 : 10) to be administered by the subcutaneous and intramuscular routes to cattle. A doramectin pour-on preparation is licensed to be used in cattle at 0.5 mg/kg. Recently, a concentrated long-acting formulation of doramectin (3.5%) was launched to be used in cattle at 700 μg/kg. This formulation supplies an extended persistence of antiparasitic action against nematodes and the main ectoparasites affecting cattle.

Moxidectin is available to be administered as injectable, pour-on (cattle) and oral (sheep and horses) formulations. A 1% nonaqueous moxidectin formulation is currently available for subcutaneous injection in cattle, sheep (0.2 mg/kg), and pigs (0.3 mg/kg). Novel moxidectin long-acting preparations for use in sheep (2%) and cattle (10%) are now available for use at higher dose rates (1 mg/kg) to cover extended antiparasitic protection periods (between 60 and 150 days). A long-acting sustained-release injectable formulation for dogs (0.17 mg/kg) designed to prevent *D. immitis* infection is currently available. A moxidectin gel preparation to be administered orally at 0.4 mg/kg to horses is also available in the veterinary pharmaceutical market.

Eprinomectin is approved as a topical formulation for use in beef and dairy cattle. Both the eprinomectin and moxidectin pour-on formulations are now indicated in lactating dairy cows with zero milk withdrawal time in some countries. Selamectin is formulated as a solution (6 and 12%) in an isopropyl alcohol/dipropylene glycol methyl-ether vehicle to be used in dogs and cats at a dose range between 6 and 12 mg/kg (Bishop et al., 2000).

Drug and Host-Related Factors Affecting Pharmacokinetics and Efficacy in Ruminants

As described in this chapter, the MLs are highly lipophilic substances that dissolve in most organic solvents. They are large molecules and despite possessing two sugar rings and two hydroxyl groups (avermectins) are relatively insoluble in water. Moxidectin solubility in water is greater than that of ivermectin and doramectin. These and other physicochemical differences between the ML molecules may account for differences in formulation flexibility and in their resultant kinetic behavior. The vehicle in which the endectocide compounds are formulated may play a rate-limiting role in their absorption kinetics and resultant plasma availability. The plasma profiles of ivermectin (Lo et al., 1985) and doramectin (Wicks et al., 1993) in cattle have been shown to be substantially affected by the composition of the administered formulation. Following parenteral administration, the low solubility of ivermectin and doramectin in water, and its deposition in subcutaneous tissue, favor a slow absorption from the injection site and provide prolonged duration in the bloodstream. Lanusse and coworkers (1997) characterized the comparative plasma disposition kinetics of ivermectin, moxidectin, and doramectin after their subcutaneous administration of the formulations commercially available for administration to cattle. While ivermectin was administered as the nonaqueous (60% propylene glycol/40% glycerol formal) preparation, an oil-based formulation of doramectin containing sesame oil/ethyl oleate (90 : 10) was administered to the experimental animals. The absorption of moxidectin, administered as an aqueous-based solution, from the site of subcutaneous injection was significantly faster than those of ivermectin and doramectin. The low solubility and the deposition of the ivermectin and doramectin nonaqueous preparations in the subcutaneous tissues favor a slow absorption from the site of injection, which may account for their prolonged residence in the bloodstream in cattle.

Several generic formulations of ivermectin have been introduced into the pharmaceutical market in different regions of the world after the expiration of the original patent of the first approved (innovator) ivermectin formulation (Ivomec®, Merial). Most of the available ivermectin generic preparations (some of them are now very well established in the pharmaceutical market) contain basically the same vehicle composition used in the innovator ivermectin formulation, but information on the comparative kinetic behavior of generic preparations in standardized pharmacokinetic trials is scarce. Lifschitz et al. (2004) found marked differences on the absorption kinetics of ivermectin given by subcutaneous injection

Table 41.2 Drug and host-related factors affecting the kinetics and efficacy of the macrocyclic lactones in ruminants

Pharmacokinetic modifications ↓ Changes in drug concentrations in target tissues ↓ Modified efficacy and/or antiparasitic persistence	Type of drug formulation Route of administration Licking behavior (topical treatment) Animal species Animal breed Nutritional condition and/or body composition Type of diet and/or level of feed intake (oral treatment) Parasitism and/or modified gastrointestinal transit time P-GP-mediated changes on drug absorption and/or excretion

The drug and host-related factors listed on the right may induce pharmacokinetic modifications resulting in modified drug efficacy/persistence. See the text for further explanation.

to cattle as four different generic (1%) formulations. The composition and quality of the vehicles and/or excipients used in the pharmacotechnical elaboration of ML formulations may be relevant to its pharmacokinetic behavior. The differences observed on the systemic availability and drug disposition kinetics among generic formulations may be reflected in the efficacy and persistence of their antiparasitic activity. Since the direct relationship between time of persistence of drug concentrations and extended efficacy against endo- and ectoparasites has been demonstrated, slight differences in formulation account for changes to the plasma kinetics and exposure of target parasites to active drug concentrations. This study was useful to build up a "conscience" on the relevance that the switchability among generic ML formulations might have on parasite control. Considering the necessary precautions to be adopted to avoid/delay the development of ML resistance in cattle nematode parasites, standardized quality control of generic formulations may greatly contribute to optimized drug use.

A number of factors affecting drug kinetics and the persistence of the antiparasitic efficacy of the ML have been identified. Among them are the animal species/breed, level of feed intake, nutritional status/body composition, influence of parasitism, formulation of dosage form, route of administration, etc. (reviewed by Lanusse and Prichard, 1993; McKellar and Benchaoui, 1996; Hennessy and Alvinerie, 2002) (Table 41.2). A series of relevant studies to compare the plasma profiles of ML in different species have been reported (Alvinerie and Galtier, 1997). From those comparisons, the consistently lower systemic availability of moxidectin (oral treatment) and ivermectin (subcutaneous treatment) observed in goats compared to sheep, emerges as a relevant finding. The influence of the route of administration on the plasma availability of the MLs has been extensively studied in ruminant species. For instance, both ivermectin and moxidectin are markedly less absorbed following oral administration to sheep compared to their subcutaneous injection. The reduced systemic availability observed following oral treatment accounted for lower milk residues excretion in orally treated dairy sheep compared to those observed after the injectable treatment (Imperiale et al., 2004b), which may be considered advantageous in required withdrawal times extension.

In the past, shortly after introduction of ivermectin into the market, nematode susceptibility to ivermectin was high and equivalent efficacy patterns were observed against abomasal parasites following its parenteral and oral administrations. However, after the oral administration of MLs to lambs infected with resistant parasites, the efficacy was higher compared to that obtained after subcutaneous treatment (Gopal et al., 2001; Alka et al., 2004; Lloberas et al., 2012). Similar results were obtained in cattle, where the oral administration of moxidectin achieved a higher efficacy against resistant nematodes compared to the subcutaneous treatment (Leathwick and Miller, 2013). The enhanced drug concentrations measured at the abomasal content after the oral administration of MLs, accounted for the greater amount of drug recovered from nematodes such as *H. contortus* (Figure 41.9). These high drug concentrations recovered in the gastrointestinal tract during the first 2–3 days after oral treatment may have a relevant effect against resistant worms, as it is of great importance to induce the pharmacological action at the target site. The increment on drug exposure obtained after the oral treatment (compared to the parenteral administration) may be useful to kill heterozygous resistant parasites present in the earliest phases of the development of resistance.

The ML has been traditionally administered by subcutaneous injection to cattle. However, formulations for their topical administration (pour-on) are currently marketed worldwide. Some practical advantages of topical compared to other routes of administration have accounted for its great acceptance for parasite control in cattle. Some information is available on the plasma kinetic behavior of avermectins given topically to cattle (Gayrard et al., 1999). The plasma and tissue disposition kinetics of moxidectin and doramectin (Sallovitz et al., 2003, 2005) administered as a pour-on to cattle has been characterized. Lower moxidectin and doramectin plasma concentrations were measured following topical

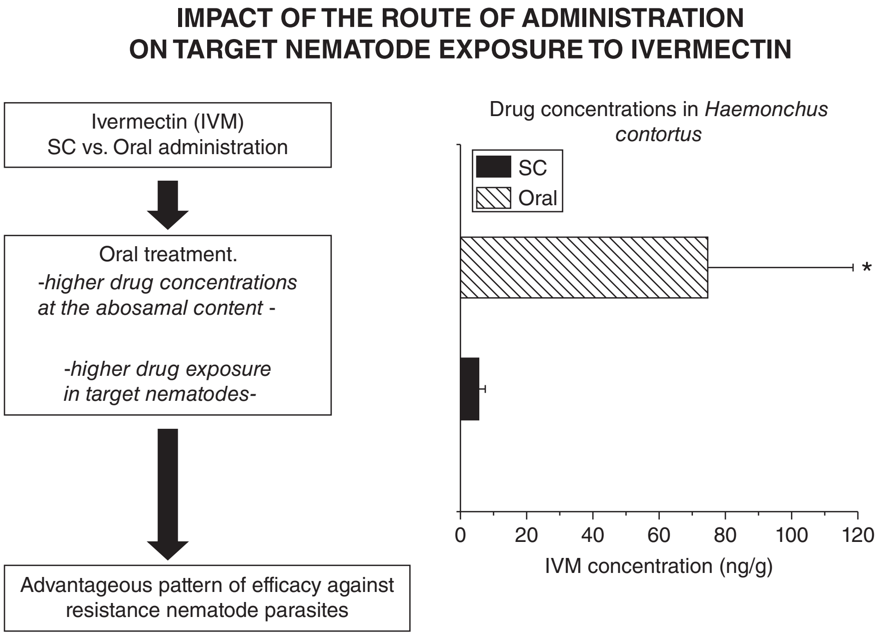

Figure 41.9 Influence of the route of administration on ivermectin exposure to target nematode parasites. Source: Data from Lloberas et al., 2012. The plot on the right side shows the ivermectin concentrations at day 3 posttreatment.

treatment compared to the subcutaneous injection of both compounds in cattle in spite of the use of a 2.5-fold higher dose rate for the pour-on administration (Figure 41.10). The absorption rate of topically administered moxidectin and its plasma availability were significantly higher in Holstein compared to Aberdeen Angus calves (Sallovitz et al., 2002), which may have considerable practical implications in terms of drug activity/persistence. Topically administered moxidectin is extensively distributed to different target tissues, including gastrointestinal mucosas, lungs, and different dermal layers. A cutaneous depot of the topically administered drug accounts for slow and sustained absorption, and agrees with the high moxidectin and doramectin

	MXD availability (AUC, ng.day/g)	
	Pour-on	SC
Skin	1224	380
Hypodermic tissue	284	61

Figure 41.10 Comparative plasma concentration profiles and total drug (expressed as AUC values) recovered in skin and hypodermic tissue after the subcutaneous (SC) and pour-on administrations of moxidectin (MXD) at recommended doses to cattle. The data illustrate the cutaneous depot of MXD after topical treatment. Source: Data from Lifschitz et al., 1999a; Sallovitz et al., 2003.

concentrations measured in the epidermis and dermis of the skin from different anatomical regions.

It has been shown (Laffont et al., 2001) that the plasma and fecal disposition of ivermectin topically administered to cattle is markedly influenced by the natural licking behavior of treated animals. Higher and more variable systemic availability of ivermectin was observed in licker cattle, compared to animals whose licking behavior was prevented. Sallovitz et al. (2005) showed that a 2-day long licking prevention period after the pour-on treatment was sufficient to significantly reduce the doramectin concentrations measured in plasma during the first 9 days posttreatment. The animals in the free-licking group ingested topically administered doramectin by self and/or allolicking, which accounted for the higher peak concentration observed in plasma as well as for the enhanced drug availability compared to the licking-restricted animals. Laffont et al. (2003) demonstrated that after the topical administration of ivermectin to cattle, drug absorption through the gastrointestinal tract due to licking-induced oral ingestion is more important than the transdermal absorption in determining drug systemic concentrations. Thus, a more complete absorption of the MLs in the gastrointestinal tract following oral ingestion of topically administered formulation, compared to cutaneous permeation, considered as the only absorption process in nonlicking animals, would explain the enhanced plasma profiles measured in calves allowed to lick freely. Licking prevention during 10 days posttreatment permitted the identification of marked changes on the doramectin concentration profiles both systemically and, much more importantly, in the gastrointestinal tract. Doramectin concentrations in luminal contents from the intestine were markedly higher in free-licking cattle (Figure 41.11). Doramectin concentrations were higher in the fluid contents than in the mucosas in the licking group. Conversely, in licking-restricted calves, doramectin concentrations were higher in the mucosal tissue than in luminal content of the different gastrointestinal sections. These observations in nonlicking calves are in agreement with the data reported by Lifschitz et al. (2000) after the subcutaneous administration of doramectin, where after absorption into the systemic circulation, the drug can reach the gastrointestinal lumen by a distribution exchange between the bloodstream and the digestive compartment, which must occur through the mucosal layer of the intestine.

On the face of the observed variations on antiparasitic response and with the threat of resistance development, the use of pour-on formulations to control endo- and ectoparasites should be carefully considered. As suggested by Bousquet-Mélou et al. (2004), there are many therapeutic, practical, and regulatory issues to be discussed on the basis of the altered pharmacokinetic behavior induced by the natural licking in pour-on treated cattle. When topical ivermectin-treated and untreated heifers were put together after treatment, the licking behavior induced partial efficacy in untreated animals. Therefore the use of pour-on formulation to develop the selective treatment strategy should be carefully evaluated as the untreated animals may be underexposed to the drug transferred from the treated animals (Bousquet-Mélou et al., 2011). It has been suggested that the inter- and intraanimal variability associated with licking behavior should be considered as a biological fact influenced by social, nutritional, physiological, pathological, environmental, and management factors. As a consequence, it is recommended that the pharmacoparasitological evaluation of pour-on products

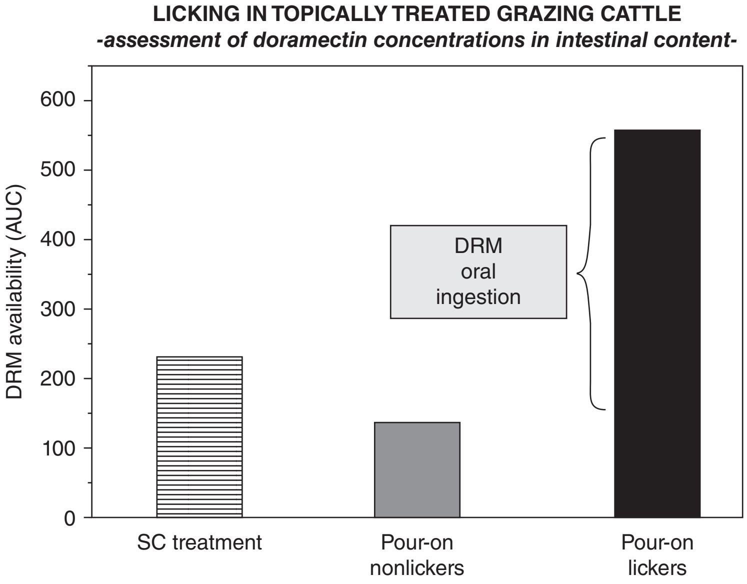

Figure 41.11 Influence of animal's licking behavior on the intestinal availability of topically administered doramectin (DRM) in grazing cattle. The data shows the AUC values obtained for DRM in the duodenal content after its topical administration (0.5 mg/kg) in both nonlickers (licking restricted over 10 days posttreatment) and free-licking calves. The comparison with the values obtained for the subcutaneous treatment (0.2 mg/kg) is included. DRM intestinal availability was significantly higher in licker calves due to licking-induced oral ingestion of the topical formulation. See the text for further explanation. AUC values are expressed in ng.day/ml. Source: Data from Sallovitz et al., 2005.

in cattle be conducted when animals are not prevented from allo- and self-licking (Toutain et al., 2012).

Tissue Residues and Withdrawal Times

Based upon teratogenicity studies in mice and from multigeneration studies in rats, the no-effect level (NOEL) of 0.2 mg/kg/day has been established. Using this NOEL to determine residue tolerances in edible tissues from pharmacokinetic studies (see Chapter 61 for a full discussion of how these values are determined), the current withholding periods for sheep and cattle have been established. However, due to their high potency and elimination through milk, the classic injectable ML formulations are contraindicated for use in animals that produce milk for human consumption. The MLs are highly lipophilic substances extensively distributed to different tissues. The highest tissue residue concentrations in food-producing animals are recovered from the liver and fat. Regulatory agencies (US Food and Drug Administration, European Agency for the Evaluation of Medicinal Products) have established the maximum residue levels (MRL) in target tissues (liver and fat) for some of the ML compounds in sheep and beef cattle. A 100 μg/kg MRL value for ivermectin in liver and fat tissue has been set. The MRL values established for doramectin are 100 μg/kg (fat) and 150 μg/kg (liver). Higher MRL values were proposed for moxidectin in fat (500 μg/kg) and eprinomectin in fat (250 μg/kg) and liver (1500 μg/kg).

Posttreatment withdrawal periods have been established for the commercialized formulations in the different food-animal species. Although the established withdrawal times may vary according to the policies applied by the regulatory agencies in different countries, the classic 1% cattle injectable formulations of abamectin, ivermectin, doramectin, and moxidectin require withdrawal times ranging from 35 up to 50 days. A 120-days period is required to consume tissues from cattle treated with the 3.15% long-acting ivermectin formulation. An 84-days posttreatment period is required to deplete moxidectin below the established tolerance limits for different tissues after its administration as a long-acting preparation (10%) in cattle subcutaneously injected in the base of the ear. Withdrawal times between 10 and 15 days are required to consume meat from sheep treated with the ivermectin oral drench. In the USA, a 45-day (35 days in Europe) withdrawal period is required for beef cattle treated with the available doramectin topical preparation. Required meat withdrawal times for doramectin in pigs parenterally treated are, at present, as follows: 24 days (USA), 28–50 days (Latin America) and 28–77 days (European countries) posttreatment. Detailed information on posttreatment withholding periods for the different ML formulations approved for use in food-producing animals in the USA can be found in the web site for the US Pharmacopeia (www.usp.org). There are no established withdrawal times for goats because MLs are not approved for use in this species. If ivermectin is administered to goats as a single extralabel oral dose of 0.2 to 0.4 mg/kg, evidence has been compiled by the Food Animal Residue Avoidance Databank (FARAD) that suggests a meat withdrawal time of 14 days and a milk withholding time of 9 days, which would be sufficient to avoid potentially harmful residues (Baynes et al., 2000).

Use of all the ML injectable formulations are restricted in lactating dairy animals. However, a pour-on formulation of eprinomectin is approved for topical use in all cattle, including lactating dairy cows, without any milk withdrawal period. A moxidectin pour-on formulation is now available for use in dairy cattle with zero withdrawal time in milk. Additionally, generic ivermectin topical preparations are now approved for use in dairy cattle without milk withdrawal in some specific countries. Milk MRL values have been established for ivermectin (10 μg/kg), eprinomectin (20 μg/kg), and moxidectin (40 μg/kg).

Safety and Toxicity

The ML compounds given at recommended therapeutic doses are highly safe compounds in the majority of the target animal species. These large safety margins are based on the selectivity of their pharmacodynamic action. A GABA-mediated action in the mammalian central nervous system may be responsible for the neurotoxicity observed when large toxic doses of different ML are administered (Lankas and Gordon, 1989). In general, the avermectins have at least a 10-fold safety margin in ruminants, horses, swine, and most dog breeds, except collies and some Australian shepherds. The signs of acute toxicity include depression, ataxia, tremors, salivation, mydriasis, and in severe cases, coma and death. No effect on breeding performance, semen quality, or pregnancy was observed when bulls or cows were treated with ivermectin at 0.4 mg/kg (Campbell and Benz, 1984). Avermectins are safe for use in cows during all stages of pregnancy. A twofold increase in dosage and multiple dosing have not adversely affected spermatogenesis, conception, longevity of gestation, or fetal development. Abamectin is slightly more toxic than ivermectin, with an oral LD_{50} in mice (14–24 mg/kg) lower than that of ivermectin (25–40 mg/kg). Signs of toxicosis were observed in cattle treated subcutaneously with abamectin at levels of 2–8 mg/kg. Abamectin is not recommended for use in calves under 4 months of age (Pulliam and Preston, 1989). No adverse effects were observed in different tolerance studies using up to 25-fold the therapeutic dose of doramectin injectable in cattle. Numerous field trials corroborate that eprinomectin is safe to use in cattle of all breeds and ages. As for the avermectins, milbemycin compounds have a wide therapeutic margin. No adverse effects have been observed in cattle subcutaneously treated with moxidectin up to 10 times the recommended dose (2 mg/kg). Moxidectin is safe in breeding animals. At three times the recommended dose (0.6 mg/kg) no adverse effects on reproductive performance of bulls and pregnant cows were observed. A different degree of neurotoxicosis was observed for moxidectin and ivermectin. Moxidectin has a 2.7-fold lower neurotoxic potential compared to ivermectin (Janko and Geyer, 2013). Moxidectin had a lower brain-to-plasma concentration ratio and entrance into the brain also causes a lower potentiation of GABA action (Ménez et al., 2012). The differences in the accumulation in the brain and in the interaction with GABA receptors may explain the differential neurotoxicity observed for both drugs.

As described in Section Mechanism of Action: Ecto–Endoparasiticadal Activity, P-GP is a transport protein that acts as a multidrug efflux pump reducing intracellular concentration of different drugs, including the MLs. The activity of this transmembrane protein, located in brain capillary endothelial cells, intestinal epithelial cells, biliary canalicular cells, renal proximal tubular epithelial cells, as well as placental and testicular cells, is related to the toxicity of the MLs. Its presence in the blood–brain barrier limits the entry of these antiparasitic molecules into the central nervous system. The accumulation of ivermectin in the brain of genetically engineered P-GP-deficient mice was 87-fold higher compared to normal mice (Schinkel et al., 1994). Certain Collie dogs are more sensitive to high doses of ivermectin than other dogs and develop signs of toxicity with single doses as low as 0.1 mg/kg (Fassler et al., 1991). The higher ivermectin brain concentrations reported in the avermectin-sensitive collies versus nonsensistive dogs may be related to a limited P-GP expression (Mealey et al., 2001; Roulet et al., 2003). A four base-pairs deletion in the *MDR1* (multidrug resistance) gene in sensitive Collie dogs seems to account for altered P-GP synthesis. Dogs homozygous for a mutant allele of *MDR1* have a nonfunctional P-GP (Mealey et al., 2001). A sample population study of 40 Collie dogs in the northwestern United States found 35% to be homozygous for the mutation and 42% to be heterozygous carriers of the mutant allele (Mealey et al., 2002). A gene study of subpopulations has shown that the mutation of the *MDR1* gene can be found in members of breeds other than Collie dogs (Australian Shepherds, English Shepherds, Shetland Sheepdogs, etc.), generally at a much lower frequency (Hadrick et al., 1995). Pharmacogenomics are more fully discussed in Chapter 50.

Animal deficient in P-GP expression in the intestine may also absorb more drug after oral treatment, which may result in higher blood concentrations and enhanced potential for neurotoxicity (Shoop and Soll, 2002). Additionally, limited P-GP expression in the hepatobiliary tract may result in a decrease bile excretion of the ML compounds. Selametin was evaluated in dogs and cats at 10 times the recommended doses and no adverse reactions were observed (Novotny et al., 2000; Krautmann et al., 2000). Selamectin use is also safe in ivermectin-sensitive Collie dogs. No abnormalities were observed in sensitive Collies treated topically with selamectin at 40 mg/kg. Milbemycin oxime is well tolerated in dogs, including Collies. Clinical signs are only seen after the administration of a 10-fold overdose. Overall, as suggested by Shoop and Soll (2002), the wide safety margin is based on the low therapeutic doses and to the fact that mammals do not have glutamate-gated chloride channels (the specific site of action for the MLs in target parasites). Additionally, these drugs do not cross the blood–brain barrier. The presence of P-GP in the blood–brain barrier, as well as in other tissues, serves as an important protective biological barrier to any adverse effects of the MLs.

Ecotoxicological Impact

The evaluation of the pattern of fecal elimination of different ML compounds administered by different routes to cattle have received special attention, due to the potential negative environmental impact caused by the effect of the drugs against dung-degrading insects, which has been evaluated under different conditions, initially for ivermectin (Lumaret et al., 1993; Herd, 1995) and then for other MLs (Suarez et al., 2003). The prolonged presence of these molecules in the feces of treated cattle produces an adverse effect against invertebrate organisms that have a relevant role on dung degradation and nutrients recycling to the soil (Strong, 1993). The residues of ivermectin and abamectin in feces not only affect the development and reproduction of adults *Coleoptera* but also are toxic against larval stages between 2 and 4 weeks after an injectable treatment (Strong and Wall, 1994; Herd, 1995). The consequences of this toxicity over the ecosystem are not fully understood. Moxidectin has been considered to be a less harmful compound compared to the avermectin-type compounds following standard injectable treatments. The lower fecal concentrations measured after moxidectin treatment in cattle compared to those obtained after ivermectin and doramectin administration (Lifschitz et al., 1999a), with a possible higher rate of environmental degradation of moxidectin, may determine its lower toxicity against dung fauna. Further research is required to evaluate potential adverse environmental impact of the ML compounds under a variety of conditions. Long-term investigations under different field production systems are particularly needed.

Concluding Remarks

The discovery of avermectins and the commercial launch of ivermectin as an ecto-endoparasiticidal agent in the early 1980s were great breakthroughs within veterinary therapeutics, which was successfully followed by the development of other avermectin and milbemycin compounds. The MLs from both chemical families combine excellent spectrum with safety, potency, and persistence. They are highly efficacious antiparasitic agents for use in a variety of livestock and companion animal species. The observations highlighted in this chapter on the phamacokinetic/pharmacodynamic relationship for MLs provide the pharmacological knowledge required to improve their therapeutic use. Avoiding misuse of the MLs is critical to delay the development of resistance. The integrated assessment of the drug disposition kinetics in the host, the processes of drug diffusion into different target parasites, and the use of pharmaceutical technology to improve drug delivery at the site of infection, are key research areas within the pharmacology of the antiparasitic drugs.

Antiprotozoan Drugs

Jennifer L. Davis and Jody L. Gookin

Numerous chemotherapeutic agents are known to possess activity against parasitic protozoa (Tables 42.1 and 42.2). Although antiprotozoal activity is characteristic of many different chemical groups, most possess a rather narrow spectrum of activity. This is in contrast to antibacterial agents, which are effective against a wide variety of organisms. This chapter presents the clinically relevant antiprotozoan drugs used against the more important protozoal disease agents of domesticated animals.

Nitroimidazoles

Spectrum: *Giardia lamblia, Balantidium coli, Entamoeba histolytica, Tritrichomonas foetus, Pentatrichomonas hominis, Trichomonas gallinae, Histomonas maleagridis, Trypanosomas spp.*

Drugs included: metronidazole, tinidazole, ronidazole, dimetridazole, ornidazole, carnidazole, benznidazole, ipronidazole, and secnidazole (Figure 42.1).

Many of these important agents were used in the treatment of poultry flagellates, and all except metronidazole and tinidazole have been removed from the market in the United States. Nitroimidazoles are suspected mutagens and carcinogens; therefore their use in food-producing animals has been strictly prohibited by the US FDA. (Legal control of veterinary drugs is discussed in more detail in Chapter 55.) For companion, exotic, and zoo animals, metronidazole is the most commonly used agent in this group and the most studied.

It is convenient to think of the mode of action of nitroimidazoles as occurring in four successive steps (Finegold and Mathisen, 1990). First is entry into the protozoan cell, second is reductive activation, third is toxic effect of reduced intermediates, and fourth is release of inactive end products. The protozoal toxicity is due to short-lived intermediates or free radicals that produce damage by interacting with DNA and possibly other molecules. The cytotoxic intermediates decompose to nontoxic and inactive compounds.

Metronidazole

Metronidazole (Flagyl® and generic) is a weak base that is moderately lipophilic. It has a low molecular weight compared to other drugs (MW 171), which facilitates penetration across membranes. The oral absorption in most animals is almost complete and it reaches high concentrations in the tissues; therefore it is active against both luminal and extraluminal protozoa (Finch and Snyder, 1986). Bioavailability of metronidazole is good in most species. In the horse, the bioavailability ranges from 75 to 116% and is not affected by feed (Britzi et al., 2010; Steinman et al., 2000; Sweeney et al., 1986). Similarly, bioavailability is complete in foals; however, pharmacokinetics are age dependent, with reduced clearance noted in younger animals (Swain et al., 2015). In the dog, it is reported to be 60–100% (Neff-Davis et al., 1981). It has a half-life of about 6–8 hours, and less than 20% binds to plasma proteins. It is metabolized in the liver by oxidation and glucuronide formation and is excreted primarily by the kidneys. Small amounts may be found in saliva and breast milk (Finch and Snyder, 1986).

Metronidazole is usually well tolerated, but potential adverse reactions include glossitis, stomatitis, and nausea. The most important adverse effects are vomiting, neurotoxicosis, and neurotoxicity (Longhofer, 1988). The reactions observed appear to be caused by inhibition of the γ-aminobutyric acid (GABA) neurotransmitter. At high doses (67–129 mg/kg/day) metronidazole has caused ataxia, lethargy, proprioceptive deficits, nystagmus, and seizure-like signs in dogs. Dogs have recovered if drug administration was discontinued, but it may require 1 to 2 weeks (Dow, 1988; Dow et al., 1989). However, when diazepam was administered as a treatment, recovery was much faster (Evans et al., 2003). Neurotoxicosis also has been observed in cats with high doses. Metronidazole has been shown in cats to induce DNA damage in circulating peripheral blood mononuclear cells both in vitro and in vivo in as few as 7 days of treatment. This DNA damage appears reversible as it is no longer observed 7 days after drug

Table 42.1 Summary of drugs used to treat selected protozoal diseases in animals

Protozoal disease	Protozoa	Species	Drug class	Drug and dosing regimen
Giardiasis	*Giardia duodenalis, G. intestinalis, G. lambia*	Dogs	Nitroimidazoles	Metronidazole: 12–15 mg/kg PO q12h for 8 days Tinidazole: 15 mg/kg PO q12h
			Benzimidazoles	Albendazole: 25 mg/kg q12h for 2 days Fenbendazole: 50 mg/kg q24h for 3 days Febantel, pyrantel, and praziquantal: febantel (26.8–35.2 mg/kg), pyrantel (26.8–35.2 mg/kg), praziquantel (5.4–7 mg/kg) PO q24h for 1–3 days
		Cats	Nitroimidazoles	Metronidazole: 22–25 mg/kg PO q12h for 5–7 days Tinidazole: 15 mg/kg PO q24h Secnidazole: 30 mg/kg PO q24h
			Benzimidazoles	Fenbendazole: 50 mg/kg q24h for 5 days Febantel, pyrantel, and praziquantal: febantel (56.5 mg/kg), pyrantel (11.3 mg/kg), and praziquantel (37.8 mg/kg) PO q24h for 5 days
		Horses	Nitroimidazoles	Metronidazole: 5 mg/kg PO q8h for 10 days
		Cattle	Benzimidazoles	Albendazole: 20 mg/kg PO q24h for 3 days Fenbendazole: 5–20 mg/kg PO q24h for 3 days
			Aminoglycosides	Paromomycin: 75 mg/kg PO q24h for 5 days
Trichomoniasis	*Tritrichomonas foetus, Pentatrichomonas hominis, Trichomonas gallinae*	Cats	Nitroimidazoles	Tinidazole: 30 mg/kg PO q24h for 14 days Ronidazole: 30 mg/kg PO q24h for 14 days
		Cattle	Nitroimidazoles	Metronidazole: 75 mg/kg IV q12h for 3 doses[a]
		Pigeons	Nitroimidazoles	Metronidazole: 40–60 mg/kg orally once a day for 5 days Ronidazole: 5 mg/kg orally once a day for 14 days Carnidazole: 20 mg/kg orally once
Trypanosomiasis	*Trypanosomas cruzi*	Dogs	Nitroimidazoles	Benznidazole: 5–7 mg/kg PO q24h for 2 months
			Nitrofurans	Nifurtimox: 2–7 mg/kg PO q6h for 3–5 months
		Cattle	Diamidene derivatives	Diminazene diaceturate: 3.5–7 mg/kg IM
Babesiosis	*Babesia divergens,*	Dogs	Tetracyclines	Doxycycline: 10 mg/kg PO q12h for 11 days (*B. canis*) Doxycycline (7–10 mg/kg, q12h) in combination with enrofloxacin (2–2.5 mg/kg, q12h) and metronidazole (5–15 mg/kg, q12h) for a duration of 6 weeks (*B. gibsoni*)
	B. equi, B. caballi, B. bigemini, B. canis		Hydroxyquinolones and naphthoquinones	Atovaquone: 13.3 mg/kg PO q8h combine with azithromycin 10 mg/kg PO q24h for 10 consecutive days (*B. gibsoni*)
			Diamidene derivatives	Diminazene diaceturate: 3.5–5 mg/kg BW IM (*B. canis*); 3.5 mg/kg q12h for 2 treatments (*B. gibsoni*) Pentamidine isethionate: 16.5 mg/kg IM on 2 consecutive days Phenamidine isethionate: 15–20 mg/kg SC q24h for 2 days (*B. gibsoni*); 8–13 mg/kg SC once (*B. canis*) Imidocarb dipropionate: 7.5 mg/kg SC (*B. canis*); 3.5 mg/kg diminazene followed by 6 mg/kg imidocarb on the following day (*B. canis*)
		Horses	Tetracyclines	Chlortetracycline: 0.5–2.6 mg/kg IV q24h for 6 days (*B. equi*)
			Diamidene derivatives	Diminazene diaceturate: 3–5 mg/kg IM q12h for 2 treatments (*B. caballi*); 6–12 mg/kg IM (*B. equi*); 0.5 mg/kg IM (*B. bigemina*) Phenamidine isethionate: 8.8 mg/kg IM q12h for 2 treatments Amicarbalide: 8.8 mg/kg IM q12h for 2 treatments (*B. caballi*) Imidocarb dipropionate: 1–2 mg/kg IM q12h for 2 treatments (*B. caballi*); 4 mg/kg IM q72h for 4 treatments (*B. equi*)
		Cattle	Tetracyclines	Oxytetracycline: 20 mg/kg IM every 4 days for 3 weeks (*B. divergens*)
			Diamidene derivatives	Diminazene diaceturate: 3–5 mg/kg IM (*B. bigemina* and *B. bovis*) Pentamidine isethionate: 0.5–2 mg/kg SC Phenamidine isethionate: 8–13 mg/kg IM q12h for 2 treatments Amicarbalide: 5–10 mg/kg IM Imidocarb dipropionate: 1–3 mg/kg IM or SC

Table 42.1 (*Continued*)

Protozoal disease	Protozoa	Species	Drug class	Drug and dosing regimen
Cryptosporidiosis	*Cryptosporidium parvum*	Cats	Aminoglycosides	Paromomycin: 165 mg/kg PO q12h for 5 days[b]
			Nitrothiazole derivatives	Nitazoxanide: 75 mg/kg PO once
		Cattle	Aminoglycosides	Paromomycin: 12.5–50 mg/kg PO q24h for 12 days
			Azalides	Azithromycin: 1500–2000 mg/calf/day PO for 7 days
			Nitrothiazole derivatives	Nitazoxanide: 1.5 g suspended in water and given orally q12h
			Alkaloids	Halofuginone: 100 μg/kg BW PO q24h for 7 days
		Goats	Aminoglycosides	Paromomycin: 50 mg/kg PO q12h for 10 days
Leishmaniasis	*Leishmania donovani, L. infantum, L. chagasi*	Dogs	Pentavalent antimonials	Sodium stibogluconate: 30–50 mg/kg pentavalent antimony IV or SC q24h for 3–4 weeks Meglumine antimonate: 100 mg/kg IV or SC q24h for 3–6 weeks or 75 mg/kg SC q12h in combination with allopurinol at 15 mg/kg PO q12h Liposomal meglumine antimonate: 9.8 mg/kg IM or SC q24h
Hepatozoonosis	*Hepatozoon americanum*	Dogs	Aminoglycosides	Paromomycin: 20–40 mg/kg IM q24h for 15–30 days
			Hydroxyquinolones and naphthoquinones	Decoquinate: feed additive (27.2 grams/pound or 59.8 grams/kg of premix) added to moist dog food at 0.5–1.0 tablespoons per 10 kg BW twice a day
			Triazene derivatives	Toltrazuril: 5–10 mg/kg PO q12h for 5–10 days
			DHFR/TS[c] inhibitors	Trimethoprim–sulfadiazine: 15 mg/kg PO q12h combined with clindamycin 10 mg/kg PO q8h and pyrimethamine 0.25 mg/kg PO q12h for 14 days[d]
			Diamidene derivatives	Imidocarb dipropionate: 5–6 mg/kg BW SQ or IM every 2 weeks until gamonts are no longer present in blood smears
Cytauxzoonosis	Cytauxzoon felis	Cats	Diamidene derivatives	Imidocarb dipropionate: 3.5 mg/kg BW IM once then repeat 7 days later
			Hydroxyquinolones and naphthoquinones	Atovaquone: 15 mg/kg PO q8h combine with azithromycin 10 mg/kg PO q24h for 10 consecutive days
Theileriosis	*Theileria parva*	Cattle	Hydroxyquinolones and naphthoquinones	Parvaquone: 20 mg/kg IM once Buparvaquone: 2.5 mg/kg IM 1–2 times
			Alkaloids	Halofuginone: 1–2 mg/kg PO once
Equine Protozoal Myelitis	*Sarcocystis neurona*	Horses	Triazene derivatives	Diclazuril: 0.5–1 mg/kg PO q24h for 28 days, or 0.5 mg/kg PO, once every 3–4 days. Toltrazuril: 5 mg/kg PO q24h for 28 days Ponazuril: 15 mg/kg PO loading dose; 5 mg/kg PO q24h for 28 days
			DHFR/TS inhibitors	Pyrimethamine: 1 mg/kg PO q24h combined with sulfadiazine 20–30 mg/kg PO q12h for 30 days after clinical signs plateau
			Nitrothiazole derivatives	Nitazoxanide: 11.36 mg/lb (25 mg/kg) PO q24h for the first 5 days, followed by 22.72 mg/lb PO q24h for 23 days
			Hydroxyquinolones and naphthoquinones	Decoquinate: 0.5 mg/kg PO q24h combined with levamisole 1 mg/kg PO q24h for 10 days
Neosporosis	*Neospora caninum*	Dogs	DHFR/TS inhibitors	Pyrimethamine: 0.25–0.5 mg/kg PO q12h combined with sulfadiazine 30 mg/kg PO q12h for 2–4 weeks
			Lincosamides	Clindamycin: 12.5–18.5 mg/kg PO q12h for 2–4 weeks
		Cattle	Triazene derivatives	Ponazuril: 20 mg/kg PO q24h for 6 days
Toxoplasmosis	*Toxoplasma gondii*	Dogs	DHFR/TS inhibitors	Pyrimethamine: 0.25–0.5 mg/kg PO q12h combined with sulfadiazine 30 mg/kg PO q12h for 2–4 weeks
			Lincosamides	Clindamycin: 3–13 mg/kg PO or IM q8h for 2 weeks or 10–20 mg/kg PO or IM q12h for 2 weeks
		Cats	DHFR/TS inhibitors	Pyrimethamine: 0.25–0.5 mg/kg PO q12h combined with sulfadiazine 30 mg/kg PO q12h for 2–4 weeks
			Lincosamides	Clindamycin: 10–12 mg/kg PO q12h for 4 weeks or 12.5–25 mg/kg IM q12h for 4 weeks

Table 42.1 (*Continued*)

Protozoal disease	Protozoa	Species	Drug class	Drug and dosing regimen
Sarcocystis	*Sarcocystis spp.*	Dogs	Hydroxyquinolones and naphthoquinones	Decoquinate: 10–20 mg/kg PO q12h
Coccidiosis	*Eimeria sp., Isospora sp.*	Dogs	DHFR/TS inhibitors	Ormetoprim/sulfadimethoxine: 11 mg/kg ormetoprim combined with 55 mg/kg sulfadimethoxine PO for up to 23 days Trimethoprim/sulfadiazine: 5–10 mg/kg trimethoprim combined with 25–50 mg/kg sulfadiazine PO q24h for 6 days to dogs over 4 kg; dogs under 4 kg BW are given half this dosage for 6 days
			Thiamidine derivatives	Amprolium: 100–200 mg total PO q24h for 7–12 days; in drinking water (sole source) at 30 ml (9.6% solution)/gal for up to 10 days; in food at 250–300 mg (20% powder) q24h for 7–10 days
			Sulfonamides	Sulfadimethoxine: 55 mg/kg PO q24h for 1 day, then 27.5 mg/kg PO q24h for 14–20 days
			Triazine derivatives	Toltrazuril: 9 mg/kg BW PO once Ponazuril: 50 mg/kg BW PO q24h for 3 days
		Cats	Sulfonamides	Sulfadimethoxine: 55 mg/kg PO q24h for 1 day, then 27.5 mg/kg PO q24h for 14–20 days
			DHFR/TS inhibitors	Trimethoprim/sulfadiazine: 5–10 mg/kg trimethoprim combined with 25–50 mg/kg sulfadiazine PO q24h for 6 days to cats over 4 kg; cats under 4 kg BW are given half this dosage for 6 days.
			Thiamidine derivatives	Amprolium: 110–220 mg/kg PO q24h for 7–12 days; in drinking water (sole source) at 1.5 tsp (9.6% solution)/gal for up to 10 days; 150 mg/kg PO combined with sulfadimethoxine at 25 mg/kg PO q24h for 14 days.
			Triazine derivatives	Toltrazuril: 18 mg/kg BW PO once Ponazuril: 50 mg/kg BW PO q24h for 3 days

[a] The use of nitroimidazoles in food-producing animals is strictly prohibited by the US FDA. Cattle receiving metronidazole should never enter the food chain.

[b] See text for discussion of toxicity.

[c] Dihydrofolate reductase/thyamidine synthase inhibitors.

[d] Regimen should be followed up with decoquinate therapy.

withdrawal (Sekis et al., 2009). Histological evidence of peripheral neurotoxicity and hepatotoxicity were noted following long term (30 days) treatment in horses treated at doses of 30 mg/kg q 12 h orally (White et al., 1996).

Metronidazole is notoriously unpalatable. This may create difficulty for administering to difficult-to-medicate pets (cats), may be challenging to administer to horses, and the aftertaste may be accompanied by a loss of appetite.

Metronidazole Benzoate

In an attempt to provide a more palatable formulation, compounding pharmacists have provided metronidazole as an ester of benzoic acid-metronidazole benzoate, also known as *benzoylmetronidazole*. This formulation, although not approved by the FDA, is available from compounding pharmacists and has been popular for use in cats. The oral absorption is 65% and it has a half-life in cats of approximately 5 hours (Sekis et al., 2009). Metronidazole base is soluble (10 mg/ml), and has moderate lipophilicity (logP −0.02 and log D −0.27 at pH 5 and above). By contrast, the benzoate form, which is an ester, is much less soluble but more lipophilic (log P value of 2.19; log D value of 2.19 at pH 5.0 and above). The lower solubility results in less drug dissolved in the saliva of cats and therefore does not produce the degree of unpleasant taste compared to the base. The lipophilicity allows for good oral absorption from the GI tract. At a dose of 20 mg/kg of metronidazole benzoate, which is equivalent to 12.4 mg/kg of metronidazole, concentrations following the oral dose in cats were above the MIC$_{90}$ for most anaerobic bacteria for at least 12 hours and above 1 μg/ml (for more susceptible organisms) for at least 24 hours (Sekis et al., 2009). Although cats are sensitive to benzoic acid toxicity, at these dosages it is unlikely that administration of metronidazole benzoate will exceed a level to produce toxicosis in cats.

Table 42.2 Drugs licensed for the treatment of coccidiosis in food animals

Species	Drug	Trade name	Regulatory information
Chickens	Roxarsone	Ren-O-Sal®, Roxarsone 10% Type A Medicated Article, combination products available	Not for use in laying hens; 5-day slaughter withdrawal for noncombination products, no longer marketed
	Decoquinate	Deccox® Type A Medicated Article, combination products available	Not for use in laying hens; no withdrawal necessary for noncombination products
	Clopidol	Cloyden 25®, combination products available	Not for use in laying hens; 5-day slaughter withdrawal for noncombination products
	Robenidine	Robenz®, combination products available	Not for use in laying hens; 5-day slaughter withdrawal for noncombination products
	Amprolium	Amprol 25%, CORID 25% Type A Medicated Article, combination products available	No withdrawal necessary for noncombination products
	Dinitolmide	Zoamix®	Not for use in laying hens; no withdrawal necessary
	Nicarbazin	Nicarbazin, combination products available	Not for use in laying hens; 4-day slaughter withdrawal for noncombination products
	Halofuginone	Stenerol®, combination products available	Not for use in laying hens; 4-day slaughter withdrawal for noncombination products
	Lasalocid	Avatec®, combination products available	Not for use in laying hens; no withdrawal necessary for noncombination products
	Maduramicin	Cygro®	Not for use in laying hens; 5-day slaughter withdrawal for noncombination products
	Monensin	Coban®, combination products available	Not for use in laying hens; no withdrawal necessary
	Narasin	Monteban®, combination products available	Not for use in laying hens; no withdrawal necessary
	Semduramicin	Aviax®, combination products available	Not for use in laying hens; no withdrawal necessary for noncombination products
	Salinomycin	Bio–Cox®, Sacox®	Not for use in laying hens; no withdrawal necessary
	Diclazuril	Clinacox®, combination products available	Not for use in laying hens; no withdrawal necessary for noncombination products
	Ormetoprim/ sulfadimethoxine	Rofenaid®, combination products available	Not for use in laying hens; 5-day slaughter withdrawal for noncombination products
	Sulfamethazine	Sulmet® Drinking Water Solution	Not for use in laying hens; 10-day slaughter withdrawal for noncombination products
Turkeys	Roxarsone	Ren-O-Sal®, Roxarsone 10% Type A Medicated Article, combination products available	Not for use in laying animals; 5-day slaughter withdrawal for most products, no longer marketed
	Clopidol	Cloyden 25®, combination products available	Not for use in laying animals; 5-day slaughter withdrawal for noncombination products
	Amprolium	Amprol 25%, CORID 25% Type A Medicated Article, combination products available	No withdrawal necessary for noncombination products
	Dinitolmide	Zoamix®	Not for use in laying animals; no withdrawal necessary
	Halofuginone	Stenerol®, combination products available	Not for use in laying animals; 7-day slaughter withdrawal for noncombination products
	Lasalocid	Avatec®, combination products available	Not for use in laying animals; no withdrawal necessary for noncombination products
	Monensin	Coban®, combination products available	Not for use in laying animals; no withdrawal necessary for noncombination products
	Diclazuril	Clinacox®, combination products available	Not for use in laying hens; no withdrawal necessary
	Ormetoprim/ sulfadimethoxine	Rofenaid®, combination products available	Not for use in laying animals; 5-day slaughter withdrawal for noncombination products
	Sulfamethazine	Sulmet® Drinking Water Solution	Not for use in laying hens; 10-day slaughter withdrawal for noncombination products

Table 42.2 (*Continued*)

Species	Drug	Trade name	Regulatory information
Cattle	Decoquinate	Deccox® Type A Medicated Article, combination products available	Not for use in lactating dairy cattle; approved for preruminating calves; no withdrawal necessary for noncombination products
	Amprolium	Amprol 25%, CORID 25% Type A Medicated Article, combination products available	Not for use in preruminating calves; 1-day slaughter withdrawal
	Sulfamethazine	Sulmet® Oblets, Sulfamethazine sustained release bolus	Not for use in lactating dairy cattle; 8 to 10-day slaughter withdrawal for individual products
	Sulfaquinoxaline	Sulfa-nox Liquid	Not for use in lactating dairy cattle; 10-day slaughter withdrawal for noncombination products
Sheep	Decoquinate	Deccox® Type A Medicated Article, combination products available	Not for use in lactating sheep; no withdrawal necessary for noncombination products
	Lasalocid	Bovatec®, numerous others and combination products available	Not for use in breeding animals; no withdrawal necessary for noncombination products
Goats	Decoquinate	Deccox® Type A Medicated Article, combination products available	Not for use in lactating goats; no withdrawal necessary for noncombination products
	Monensin	Rumensin®	Not for use in lactating goats; no withdrawal necessary
Swine	Toltrazuril	Baycox®	Extralabel drug use, contact regulatory agencies for withdrawal times
Rabbits	Diclazuril	Clinicox®	Extralabel drug use, contact regulatory agencies for withdrawal times
	Lasalocid	Avatec/Bovatec®, numerous others and combination products available	No withdrawal necessary for noncombination products
	Sulfaquinoxaline	SQ 40% Medicated feed	10-day withdrawal
Pheasants	Amprolium	Amprol 25%, CORID 25% Type A Medicated Article, numerous others and combination products available	No withdrawal necessary for noncombination products
Chukar partridges	Lasalocid	Avatec/Bovatec®	No withdrawal up to 8 weeks of age
	Ormetoprim/ sulfadimethoxine	Rofenaid®	Not released into wild before 18 weeks and can be used only up to 8 weeks of age
Bobwhite quail	Monensin	Coban®, combination products available	Not for use in laying hens; no withdrawal necessary
	Salinomycin	Bio-Cox®, Sacox®	No withdrawal necessary
Ducks	Ormetoprim/ sulfadimethoxine	Rofenaid®	Not for use in breeding animals or animals producing eggs for human consumption; 5-day slaughter withdrawal

Please see text for further explanation of dosing and toxicities. Regulatory information is applicable to drugs used in the United States, and is current only as of the writing of this chapter. Please consult the label directions on all products prior to administration because extralabel use of feed additives is prohibited by the US FDA.

Clinical Use

Metronidazole is not approved for animal use, but is available as the base in capsules (375 mg), tablets (250 and 500 mg), or for injection as metronidazole hydrochloride in 500 mg vials. In addition to the antiprotozoal uses listed here, the major use of metronidazole in animals is for the treatment of infections caused by anaerobic bacteria. Metronidazole has a unique effect on anaerobic bacteria because of a reduction reaction to cytotoxic derivatives, a mechanism lacking in aerobic bacteria. Discussion on the antibacterial uses of metronidazole is listed in Chapter 36.

Cats: Metronidazole at a dose of 25 mg/kg orally, twice daily for 7 days has been shown to completely eliminate *Giardia* cyst shedding in cats known to be chronic shedders of a human isolate of *Giardia lamblia* (Scorza and Lappin, 2004). Metronidazole was also effective in eliminating cyst shedding as well as diarrhea associated with naturally occurring *Giardia* infections at a dose of 22 mg/kg orally, twice daily for 5 days (Zimmer, 1987).

Dogs: Metronidazole at a dose of 12–15 mg/kg orally, twice a day for 8 days is commonly prescribed for treatment of infections caused by *Giardia lamblia*, *Balantidium coli*, *Entamoeba* spp., and *P. hominis*.

Horses: Giardia infections in horses are rarely reported to cause disease; however, successful treatment has been accomplished with 5 mg/kg of metronidazole orally, three times a day for 10 days (Kirkpatrick and Skand, 1985).

Name	Chemical name (Empirical formula) [Molecular weight]	Chemical structure
Dimetridazole	1,2-dimethyl-5-nitro-1*H*-imidazole ($C_5H_7N_3O_2$) [141.13]	Ipronidazole	1-methyl-2-(1-methylethyl)-5-nitro-1*H*-imidazole ($C_7H_{11}N_3O_2$) [169.18]	Metronidazole	1-(2-hydroxyethyl)-2-methyl-5-nitroimidazole ($C_6H_9N_3O_3$) [171.16]	Ronidazole	1-methyl-2-[(carbamoyloxy)methyl]-5-nitroimidazole ($C_6H_8N_4O_4$) [200.16]	Tinidazole	1-[2-(ethylsufonyl)ethyl]-2-methyl-5-nitro-1*H*-imidazole ($C_8H_{13}N_3O_4S$) [247.26]	
Figure 42.1 Nitroimidazoles.

Cattle: Metronidazole has been used to treat trichomoniasis in bulls at a dose of 75 mg/kg IV q 12 h for up to three doses. Metronidazole (and related drugs) are strictly forbidden for use in food-producing animals. Because of regulatory issues, animals treated in this manner must never enter the food chain in the United States.

Reptiles: Metronidazole is commonly used in reptile medicine for treatment of anaerobic bacteria and protozoa infections. However, there is little guidance on dosage regimens and studies of clinical effectiveness. Generally, doses of 20 mg/kg are administered. A summary of available studies is found in the paper by Innis et al. (2007). In red-eared slider turtles the half-life was 27 hours and it reached therapeutic concentrations at a dose of 20 mg/kg (Innis et al., 2007). However, metronidazole was administered by an intracoelomic injection, which produced adverse effects in some of the turtles.

Tinidazole

Tinidazole (Tindamax^{TM}, Simplotan®, or Fasigyn®) is a second-generation 5-nitroimidazole that is FDA approved for use in treating *T. vaginalis*, *Giardia* spp., and *Entamoeba histolytica* infections in people. Tinidazole is completely absorbed after oral administration in horses, cats, and dogs (Pyörälä et al., 1990; Sarkiala et al., 1991), and has been shown to penetrate well into various tissues where drug concentrations are found to be similar to that in plasma (Wood et al., 1973). The apparent total plasma clearance of the drug is about twofold higher in dogs than in cats, resulting in an elimination half-life that is twice as long in cats (8.4 hours) than in dogs (4.4 hours) (Sarkiala et al., 1991). The elimination half-life in horses is reported as 5.2 hours (Pyörälä et al., 1990). It is metabolized in the liver by hydroxylation and glucuronide conjugation and is excreted into both urine and feces. Tinidazole has been administered to dogs at doses up to 150 mg/kg body weight for 24 weeks without toxic or adverse reactions. Dosages of 450 mg/kg body weight may result in liver enzyme elevations in dogs. Toxicity data in cats has not been reported.

Clinical Use

Dogs and cats: Tinidazole at a dose of 30 mg/kg orally once a day for 14 days has been shown to suppress shedding of *T. foetus* in experimentally infected cats (Gookin et al., 2007). Based on studies in people, tinidazole is also likely to be effective for treatment of most infections amenable to metronidazole, including *Giardia* infections in dogs and cats. Pharmacokinetic studies suggest that doses of 15 mg/kg orally twice a day for dogs or once a day for cats will produce concentrations at a level that is thought to be therapeutically effective.

Horses: Clinical use of tinidazole in horses has not been reported. Pharmacokinetic studies suggest a dose of 10–15 mg/kg orally twice a day (Pyörälä et al., 1990).

Ronidazole

Ronidazole is not approved for human or veterinary use in the United States and not available in a marketed form; however, it is considered an effective treatment for *T. gallinae, Histomonas meleagridis, Giardia*, and *T. foetus* infections. It has a tenfold higher in vivo activity against trichomonal infections compared to metronidazole (Miwa et al., 1986). The susceptibility of *Tritrichomonas foetus* has been reported in two studies (Kather et al., 2007; Gookin et al., 2006). In the study by Gookin et al. (2006) ronidazole was the most active compound tested for in vitro activity.

Clinical Use

Cats: Ronidazole at a dose of 30 mg/kg orally twice a day for 14 days has been shown to eliminate shedding of *T. foetus* in experimentally infected cats (Gookin et al., 2006). The pharmacokinetics of ronidazole has been examined in cats after IV and oral administration (LeVine et al., 2011). It was rapidly absorbed after oral administration in cats with a long terminal half-life. Although neurotoxicity has been reported from administration to cats (Rosado et al., 2007), these reactions were associated with high doses. Reports indicate that ronidazole treatment is discontinued because of signs of toxicity in approximately 5% of treated cats (Xenoulis et al., 2013). Based on the pharmacokinetic results cited above, current recommendations are to not exceed 30 mg/kg once daily in cats. In a pharmacokinetic study in which ronidazole was administered intravenously (prepared from an aqueous compounded formulation) and orally, no adverse reactions in healthy cats were observed. Resistance of *T. foetus* to treatment with ronidazole both in vivo and in vitro is increasingly recognized (Gookin et al., 2010).

Dogs: Ronidazole at a dose of 30–50 mg/kg orally twice a day for 7 days combined with environmental disinfection was reported to be effective in eliminating Giardia cyst and antigen shedding in a group of chronically infected kenneled dogs (Fiechter et al., 2012).

Pigeons: *T. gallinae* (pigeon canker) is generally treated with ronidazole (5 mg/kg orally once a day for 14 days), carnidazole (20 mg/kg orally once), or metronidazole (40–60 mg/kg orally once a day for 5 days).

Benznidazole

Benznidazole has been shown to produce cures of acute trypanosomiasis in dogs with fewer side effects than nifurtimox. Following experimental infection with *Trypanosoma cruzi*, benznidazole initially induced a potent suppression of parasitemia in treated animals. However, 12 months posttreatment, the parasite detection was similar between treated and untreated infected groups (Santos et al., 2012).

Clinical Use

Dogs: Dogs are treated with 5–7 mg/kg BW benznidazole orally at 24-hour or 12-hour intervals for 2 months (Barr, 2006; Santos et al., 2012).

Secnidazole

Secnidazole has been reported as effective for elimination of cyst shedding by cats experimentally infected with *Giardia* using a single dose given orally at 30 mg/kg of body weight. At this dose, however, cats were described as apathetic, inappetant for 48 hours after drug administration, and in a single cat an increase in measured liver enzyme activities were documented (Da Silva et al., 2011).

Pentavalent Antimonials

Spectrum: *Leishmania* spp.

Drugs included: Sodium stibogluconate, meglumine antimonate (Figure 42.2).

Pentavalent antimonials have been shown to inhibit topoisomerase in vitro (Lucumi et al., 1998) and thereby interfere with parasite replication. They also inhibit enzymes involved in the synthesis of nucleotides and inhibit phosphofructokinases, enzymes necessary for glycolytic and fatty acid oxidation (Baneth and Shaw, 2002). The in vivo mode of action of the pentavalent antimonials is still unclear. The pharmacodynamics of these drugs are still debated, and it is not known whether a better clinical response would be achieved with higher peak plasma concentrations versus prolonged time above the minimum inhibitory concentration of the protozoa (Valladares et al., 1998). Increasing resistance to pentavalent antimony compounds has been documented in recent years, and their effectiveness appears to be decreasing. In general, canine visceral leishmaniasis is more difficult

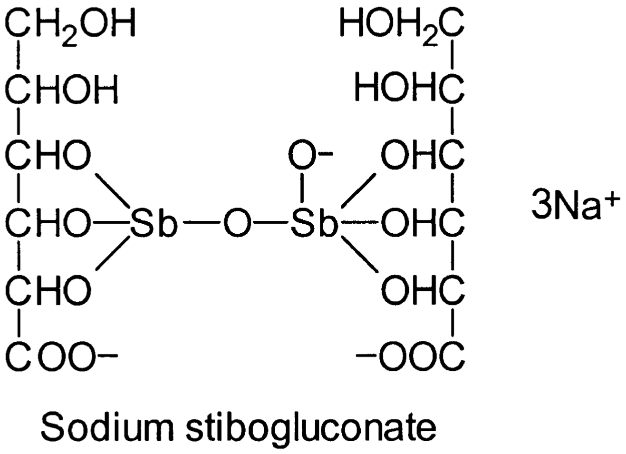

Figure 42.2

to treat than the human form of the disease. The use of pentavalent antimonials is contraindicated in patients with myocarditis, hepatitis, or nephritis. Both sodium stibogluconate and meglumine antimonate are administered on the basis of their antimony content. Paromomycin may increase the concentration of antimony compounds, thereby increasing toxicity, therefore caution is advised with coadministration (Belloli et al., 1995).

Sodium Stibogluconate

Sodium Stibogluconate (Pentostam®) was made available in the United States, from the Centers for Disease Control in 1968, for treatment of leishmaniasis in human beings (Figure 42.2). It is in aqueous solution at a concentration of 330 mg/ml of agent, which is equivalent to 100 mg/ml pentavalent antimony. Clinical formulations consist of multiple uncharacterized molecular forms, some of which have higher molecular weights than the active compound. In human beings, most of a single dose of sodium stibogluconate is excreted by the kidneys in the urine within 24 hours regardless of whether it is given IV or IM. Antimony compounds are eliminated faster if given IM than SC or IV in dogs, and it is important to maintain serum concentrations of the compound to treat leishmaniasis. Pentavalent antimonials are relatively well tolerated. Adverse reactions include pain at the injection site, gastrointestinal (GI) clinical signs, delayed muscle pain, and joint stiffness.

Clinical Use

Dogs: Canine leishmaniasis is treated with sodium stibogluconate to deliver 30–50 mg/kg BW pentavalent antimony by either IV or SC administration at daily intervals for 3–4 weeks (Slappendel and Teske, 1997). Relapses may occur a few months to a year after treatment and should be treated with another round of pentavalent antimony.

Meglumine Antimonate

Meglumine antimonate (Glucantime®) may be less likely to cause adverse effects than sodium stibogluconate. Adverse effects noted include lethargy, gastrointestinal disturbance, and injection site reactions, including muscle fibrosis and abscess formation with IM injection (Noli and Auxilia, 2005). It is available in a solution that contains 300 mg/ml antimony. Bioavailability is approximately 92% after IM or SC administration, and 80% of the drug is excreted in the urine within the first 9 hours (Valladares et al., 1997).

Liposomal encapsulated formulations of meglumine antimonite (LMA) have also been tested in dogs. They reach higher plasma concentrations, have slower clearance, and have a higher volume of distribution than regular formulations (Valladares et al., 1997). They also reach good concentrations in the bone marrow of affected dogs. Compared to conventional formulations, a positive effect on plasma total protein and gammaglobulin concentrations was seen with the LMA formulation, with no relapses noted at 12 months after treatment. Although good results have been seen with this formulation, complete eradication of the parasite is unlikely to be achieved and the product may not be cost effective when compared to conventional formulations.

Clinical Use

Dogs: Canine visceral leishmaniasis has been treated with meglumine antimonate given IV or SC at 100 mg/kg BW once daily for 3–6 weeks (Slappendel and Teske, 1997). No advantage is provided by IV administration. Relapses will occur in long-term survivors and require retreatment. Alternatively, a dosing regimen of 75 mg/kg SC twice daily achieves higher peak concentrations and maintains detectable plasma concentrations for the entire dosing interval (Valladares et al., 1998). For liposomal encapsulated meglumine antimonite, a dose of 9.8 mg/kg q 24 h is recommended (Valladares et al., 2001). Combined treatment with meglumine antimoniate and allopurinol is considered to be the most effective therapy for canine leishmaniasis (Manna et al., 2015). The combination is administered for 4 to 8 weeks, followed by treatment with allopurinol alone at a dose of 15 mg/kg orally twice a day for at least 6 to 12 months (Paradies et al., 2012). In an outbreak of cutaneous leishmaniasis in dogs in South America, empiric treatment with 14–16 mg/kg BW of meglumine antimoniate IM every day for up to 30 days resulted in good clinical cure in all dogs (n = 72), but relapses were reported 1–2 months after the end of treatment (Vélez et al., 2012).

Arsenicals

Spectrum: Histomoniasis, coccidiosis

Drugs included: Arsanilic acid, carbarsone, nitarsone, and roxarsone.

The exact antiprotozoal mechanism of action of arsenicals is not known, however these drugs nonspecifically bind to disulphide moieties in proteins, thereby inhibiting many enzyme systems that use biological ligands containing available sulfhydral groups (Blum and Burri, 2002). This mechanism is also thought to be related to the toxic effects of arsenic compounds on the host. These drugs continue to be administered to humans for treatment of African trypanosomiasis. In poultry, use of these compounds is for the prevention and treatment of histomoniasis and coccidiosis in turkeys.

Available veterinary formulations are restricted to organic arsenic compounds, as inorganic arsenic is considered carcinogenic. It has been found that organic arsenic can be converted to inorganic arsenic in vivo, resulting in detectable levels in the liver of poultry (Conklin et al., 2012). Although concentrations of inorganic arsenic are low in the tissue and unlikely to cause problems in the human food chain, this information has led to the systematic withdrawal of arsenical containing formulations from the market in the United States.

Clinical Use

Chickens and turkeys: Nitarsone (Histostat-50®) has been used as a feed additive for the prevention of histomoniasis in turkeys and chickens. It is not active if birds have been infected for more than 4 days. A 5-day withdrawal is required for nitarsone. Overdosing or lack of adequate water may result in leg weakness and paralysis in birds. Nitarsone is dangerous for ducks, geese, and dogs. Roxarsone (3-Nitro®) is fed as a growth promotant and as a preventative for coccidiosis. A 5-day withdrawal is also required for roxarsone. Like nitarsone, overdosing or lack of adequate water may result in leg weakness and paralysis in birds.

Benzimidazoles

Spectrum: Giardiasis

Drugs included: Albendazole, fenbendazole, febantel (Figure 42.3).

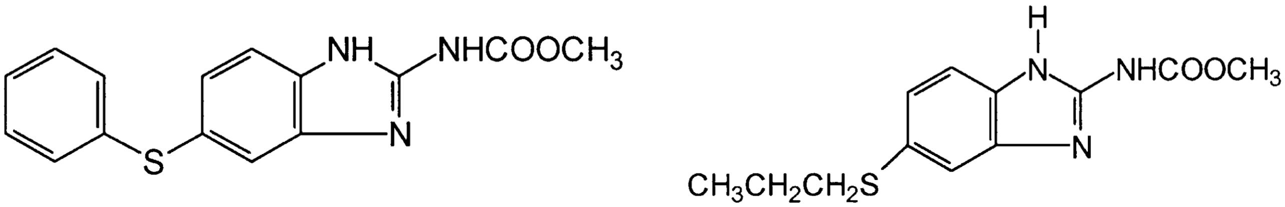
The benzimidazoles are a group of agents that are widely used in the treatment of helminth parasites of large and small animals. (Antihelmintics are discussed in detail in Chapters 39–41.) Some compounds in this group have excellent activity against *Giardia* spp. This group lacks, or has little, antibacterial activity and unlike other antigiardial agents is unlikely to interfere with intestinal microflora during treatment. The benzimidazoles are known to bind to β-tubulin subunits of microtubules and interfere with microtubule polymerization (Gardner and Hill, 2001). This causes structural changes in *Giardia* trophozoites consistent with microtubule damage to the adhesive disk and internal microtubule cytoskeleton but not the external flagella.

Albendazole

Albendazole (Valbazan®) is available in liquid and paste formulations. It is effective against *Giardia* sp. in human beings, mice, and dogs. Albendazole is poorly absorbed from the intestinal tract. Albendazole is potentially toxic, causing dose-dependent and idiosyncratic myelosuppression in dogs and cats respectively (Stokol et al., 1997). It is potentially teratogenic so it should not be given to pregnant animals. Its use in cats is not recommended.

Clinical Use

Dogs: A single oral 25 mg/kg BW treatment was not effective in clearing cysts from the feces of dogs, but dogs treated orally with albendazole at 25 mg/kg BW every



Fenbendazole
($C_{15}H_{13}N_3O_2S$)
[299.35]

Albendazole
($C_{12}H_{15}N_3O_2S$)
[265.33]

Figure 42.3

12 hours for 2 days cleared *Giardia* cysts from their feces (Barr et al., 1993). None of 32 dogs treated for giardiasis with albendazole developed adverse reactions (Barr et al., 1993).

Cattle: Albendazole given at 20 mg/kg BW orally for 3 days reduced *Giardia* cyst production by >90% in naturally infected calves (Xiao et al., 1996).

Fenbendazole

Fenbendazole (Panacur®, Safeguard®, Axilur®) is available in numerous preparations as a paste, suspension, or granules. Side effects with this drug are rare; however, vomiting and diarrhea may occur in small animals. Pancytopenia has been reported in a dog following fenbendazole administration (Gary et al., 2004). The changes were reversible with discontinuation of therapy.

Clinical Use

Dogs: Fenbendazole is effective against *Giardia* organisms in dogs if given at 50 mg/kg BW every 24 hours for 3 days (Zajac et al., 1998). More frequent dosing at 50 mg/kg BW orally every 8 hours was as effective as every 24 hours, and no adverse effects were noted (Barr et al., 1994a).

Cats: Fenbendazole at 50 mg/kg BW every 24 hours for 5 days was effective in eliminating the shedding of *Giardia* cysts in 4/8 cats coinfected with *Cryptosporidium* (Keith et al., 2003).

Cattle: Fenbendazole is also effective against *Giardia* organisms in calves when given orally at 5–20 mg/kg BW every 24 hours for 3 days (O'Handley et al., 1997; Xiao et al., 1996).

Febantel

Febantel (Drontal-Plus®, Drontal Flavour Plus®) is a benzimidazole available in a combination product with pyrantel pamoate or pyrantel embonate and praziquantel for the treatment of intestinal nematodes and cestodes in dogs and cats. Febantel is metabolized by the liver to fenbendazole and oxfendazole.

Clinical Use

Dogs: This combination has been shown to be effective to treat canine giardiasis when given orally, once daily for 1–3 days to provide praziquantel (5.4 to 7 mg/kg), pyrantel pamoate (26.8 to 35.2 mg/kg), and febantel (26.8 to 35.2 mg/kg) (Barr et al., 1998; Giangaspero et al., 2002). Strict hygiene to prevent reinfection is imperative to maximize treatment success (Payne et al., 2002). In studies of dogs naturally infected with *Giardia*, treatment with tablets containing 150 mg febantel, 144 mg pyrantel embonate, and 50 mg praziquantel at a dose of one tablet per 10 kg of body weight was effective in short-term eradication of cyst shedding (Bowman et al., 2009) and demonstrated no difference in efficacy if given orally once a day for a 3-day versus a 5-day duration (Montoya et al., 2008).

Cats: The combination product of febantel, pyrantel, and praziquantel was shown to be effective at decreasing *Giardia* cyst shedding in naturally infected kittens at doses of 56.5 mg/kg, 11.3 mg/kg, and 37.8 mg/kg, respectively, orally once a day for 5 days (Scorza et al., 2006). In addition, kittens treated at these doses were resistant to recrudescent shedding of oocysts following administration of methylprednisolone.

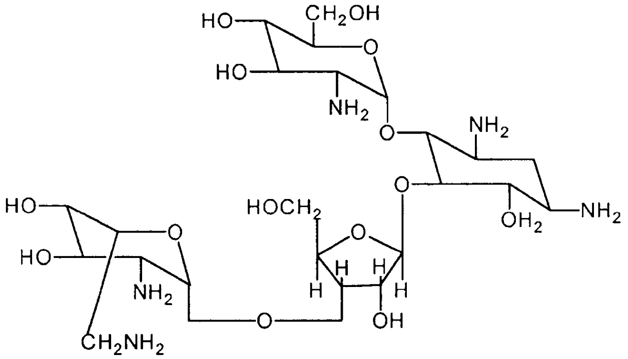
Aminoglycosides

Spectrum: *Giardia lamblia*, *Leishmania* spp., *Entamoeba* spp., *Cryptosporidium* spp.

Drugs included: Paromomycin (Figure 42.4).

Paromomycin

Paromomycin (Aminosidine®) is an aminoglycoside antibiotic that is produced by *Streptomyces rimosus*. Paromomycin interferes with bacterial protein synthesis by binding to 16S rRNA at the amino-acyl-tRNA binding site, which causes a conformational change and subsequent misreading of the mRNA and inhibition of translocation (Fourmy et al., 1998). Its anti-*Leishmania* mode



Paromomycin
($C_{23}H_{45}N_5O_{14}$)
[615.65]

Figure 42.4

of action is not known, but it has been suggested that it interferes with parasite mitochondrial activity (Maarouf et al., 1997).

Paromomycin is used in the treatment of luminal amoebiasis, leishmaniasis, and cryptosporidiosis. It has also been used in humans for the treatment of resistant giardiasis. It is poorly absorbed following oral administration, which leads to high intestinal luminal concentrations of the drug. Paromomycin has little activity against intestinal bacteria. Adverse effects include nausea, vomiting, abdominal cramps, and diarrhea. Although little is absorbed from the intestinal tract, it is eliminated via the kidneys, so its use is contraindicated in patients with renal disease. It is possible that in animals with intestinal disease, the mucosal barrier may be breached to produce more systemic absorption and potential for violative residues in food-producing species and systemic toxicity. This may have contributed to toxicity in four cats in one clinical study (Gookin et al., 1999). Coinfection with various mycotoxins, including fumonisin B1 and zearalenone, may also result in increased cellular permeability to paromomycin (Goossens et al., 2012). It also has the potential to cause reversible and irreversible vestibular, cochlear, and renal toxicity when given parenterally. Paromomycin plasma concentrations peak in the serum of dogs at 30 μg/ml about 60 minutes after IM or SC administration of a 15 mg/kg BW dose (Belloli et al., 1996). Paromomycin like other aminoglycosides has low protein binding in serum – approximately 4%.

Clinical Use

Dogs: Paromomycin given IM at 20 mg/kg BW daily for 15 days will greatly improve clinical signs of visceral leishmaniasis in dogs (Vexenat et al., 1998). Relapses may occur within 50–100 days. Administration of 15 mg/kg BW once daily, for 21 consecutive days resulted in a partial remission of the clinical signs and amelioration of clinicopathological abnormalities; however, a parasitological cure was not achieved (Athanasiou et al., 2013). Treatment with 40 mg/kg IM once daily for 30 days may enhance the cure rate of dogs (Vexenat et al., 1998). If paromomycin is administered SC with antimony, there is no effect on the pharmacokinetics of paromomycin but there is a marked effect on the pharmacokinetics of antimony (Belloli et al., 1995). Serum levels of antimony remain higher, and the dose should be adjusted to prevent toxic levels of the metal from appearing in the blood.

Cats: A naturally infected cat with cryptosporidial diarrhea was successfully treated with oral paromomycin given at 165 mg/kg BW orally every 12 hours for 5 days (Barr et al., 1994b). As mentioned previously, it can be toxic in cats if systemic absorption occurs owing to intestinal barrier disruption. It resulted in acute kidney disease, deafness, and hypermature cataract formation when given orally to four cats with *T. foetus* infection at doses as low as 70 mg/kg BW every 12 hours for 4 days (Gookin et al., 1999).

Cattle: For cryptosporidiosis, when administered at 12.5–25 mg/kg PO to calves, it delayed the onset of shedding and decreased the number of oocysts shed, while a dose of 50 mg/kg prevented oocyst shedding. Treatment of calves with oral paromomycin at 50, 25, or 12.5 mg/kg BW twice daily was effective in preventing oocyst production (50 mg/kg dose) or in delaying the onset of oocyst production and in greatly reducing the numbers of oocysts excreted (12.5–25 mg/kg BW doses) when started 1 day before inoculation and continued for 10 days after inoculation (Fayer and Ellis, 1993). For giardiasis, a dose of 75 mg/kg orally, once daily for 5 days caused a 100% reduction in cyst shedding at 9 days after initiation of treatment (Geurden et al., 2006).

Goats: Treatment of 2 to 4-day-old goat kids with oral paromomycin at 50 mg/kg BW twice daily for 10 days was effective in preventing cryptosporidiosis (Mancassola et al., 1995). Paromomycin may also have a role in treating or preventing the spread of cryptosporidiosis outbreaks in calves and goats. The anticryptosporidial activity of paromomycin apparently does not involve trafficking through the host cell cytoplasm but involves movement of the agent through altered apical membranes that surround the developing parasites (Griffiths et al., 1998). Paromomycin does not exert its effects on extracellular stages of *C. parvum* (Griffiths et al., 1998). There are no products containing paromomycin approved for use in food-producing animals in the United States; therefore, all use would be considered extralabel.

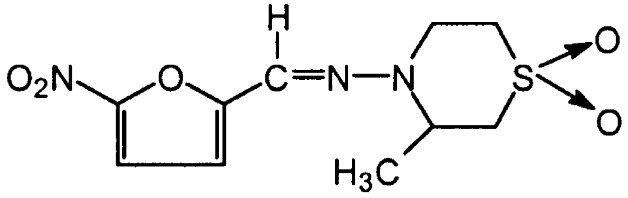
Nitrofurans

Spectrum: *Trypanosomas cruzi*

Drugs included: Nifurtimox (Figure 42.5).

Nifurtimox

Nifurtimox (Lampit®) is a nitrofuran derivative that is the most widely used agent for the treatment of human *Trypanosoma cruzi* infections (Van Reken and Pearson, 1990) and is effective against natural and experimental disease in dogs (Barr, 2006). It is marketed as 100 mg tablets, but in the United States must be obtained from the Centers for Disease Control. Mutagenicity and carcinogenicity of these compounds have been documented in laboratory animals; therefore, their use in



Nifurtimox
($C_{10}H_{13}N_3O_5S$)
[287.29]

Figure 42.5

food-producing animals, including the use of topical products, is strictly prohibited by the US FDA. (Legal control of veterinary drugs is discussed in Chapter 55.)

Its likely mode of action is through the production of activated forms of oxygen. It is reduced to the nitro anion radical in the presence of pyridine nucleotides. The anion then reacts with oxygen to produce superoxide and regeneration of nifurtimox (Finch and Snyder, 1986). This cycle continues, and the activated oxygen molecules exert their toxic effects on the parasites. This cycle is thought to be initiated by the enzyme trypanothione reductase. It has activity against amastigote and trypomastigote stages.

In human beings, nifurtimox is well absorbed after oral administration, but only low concentrations of the parent compound are found in the plasma and little is found in the tissues or urine (Webster, 1990). It is excreted in the urine in the form of metabolites. Adverse side effects occur in up to 50% of human beings treated and are associated with GI and central nervous system signs.

Clinical Use

Dogs: Canine *T. cruzi* infections are treated with 2–7 mg/kg BW nifurtimox orally at 6-hour intervals for 3–5 months (Barr, 2006). This is effective in preventing death from acute disease and extending life, but most dogs will still develop chronic cardiac disease, which is usually fatal (Barr, 2006). Improved survival has been shown in dogs concurrently treated with antiinflammatory doses of glucocorticoids (Andrade et al., 1980).

Tetracyclines

Spectrum: Amoebae, flagellates, piroplasms, ciliates.

Drugs included: Oxytetracycline, chlortetracycline, doxycycline, minocycline.

Tetracyclines represent a broad group of antiprotozoal agents, some of which have activity against amoebae, mucosal flagellates, piroplasms, and ciliates. (Chapter 34 has more detailed description of the pharmacology of tetracyclines.)

Clinical Use

Cattle: A long-acting formulation of oxytetracycline (LA/200) is useful in prophylaxis of bovine *Babesia divergens* infection if 20 mg/kg BW is given IM every 4 days for 3 weeks after exposure; 10–15 mg/kg BW given IM every 4 days causes moderation in the clinical signs (Kuttler, 1988). Tetracyclines can also be used to treat *Theileria* infections in cattle but are less effective and must be given in large doses early in the infection and used for longer periods of treatment. Product label for chlortracycline medicated feed includes control if active infection is caused by *Anaplasma marginale*. Oxytetracycline has been used in cattle for treatment of *Anaplasma marginale* infections. However, efficacy has been questionable. One study compared enrofloxacin (5 mg/kg IV q 24 h for 5 days), imidocarb (5 mg/kg IM twice, 7 days apart), or oxytetracycline (22 mg/kg IV q 24 h for 5 days) for elimination of persistent *Anaplasma marginale* infections in cattle. None of the tested treatments reliably eliminated persistent *A. marginale* infections in all cattle (Coetzee et al., 2006).

Horses: Chlortetracycline may be effective against *Babesia equi* infection in horses if 0.5–2.6 mg/kg BW is given IV daily for 6 days early in the infection (Kuttler, 1988). Oxytetracycline when administered at a dose of 5–6 mg/kg IV, once daily for 7 days was effective against *Theileria equi*, but not *Babesia caballi* (Zobba et al., 2008). Imidocarb (discussed in Section Imidocarb Dipropionate) is considered the most effective treatment for equine piroplasmosis (Wise et al., 2013).

Dogs: Doxycycline is effective at preventing clinical manifestations of *Babesia canis* infection if given at 10 mg/kg BW twice daily for 11 days (Vercammen et al., 1996). However, atovaquone in combination with azithromycin is considered the preferred treatment for *Babesia canis* in dogs (Birkenheuer, 2014). Treatment of dogs with *Babesia gibsoni* with a combination of oral doxycycline (7–10 mg/kg, q 12 h), enrofloxacin (2–2.5 mg/kg, q 12 h), and metronidazole (5–15 mg/kg, q 12 h) for a duration of 6 weeks, with and without two intramuscular injections of diminazene diaceturate (3 mg/kg, q 7 days), resulted in an overall efficacy of 85.7% and 83.3%, respectively, with a mean recovery time of 24.2 and 23.5 days, respectively (Lin et al., 2010). Combinations of clindamycin-doxycycline and metronidazole also have been used (Birkenheuer, 2014).

Hydroxyquinolones and Naphthoquinones

Spectrum: *Coccidia, Babesia* sp., *Hepatozoon americanum, Theileria* sp., *Cytauxzoon* sp., *T. gondii, Eimeria* sp., *malaria, Pneumocystis carnii.*

Drugs included: Decoquinate, atovaquone, parvaquone, buparvaquone (Figure 42.6).

The quinolone anticoccidials inhibit coccidial respiration by interfering with cytochrome-mediated electron transport in the parasites' mitochondria. The site of action of quinolone anticoccidials is probably within the bc1 complex, where the electrons are transferred from ubiquinone to cytochrome c. These compounds are coccidiostatic and allow penetration of sporozoites, but not development. These inhibited sporozoites have the ability to resume development after the agents are removed. Little anticoccidial immunity develops in chickens on these medications.

Decoquinate

Decoquinate (Deccox®) is one of the quinolone (4-hydroxyquinolones) anticoccidials. It is poorly absorbed

Name	Chemical name (Empirical formula) [Molecular weight]	Chemical structure
Buquinolate	4-hydroxy-6,7-diisobutoxy-3-quinolinecarboxylic acid ethyl ester ($C_{20}H_{27}NO_5$) [361.42]	Decoquinate	6-declyoxy-ethoxy-4-hydroxy-3-quinolinecarboxylic acid ethyl ester ($C_{24}H_{35}NO_5$) [417.53]	Nequinate	7-(benzyloxy)-6-*n*-butyl-1,4-dihydro-4-oxo-3-quinoline-carboxylic acid methyl ester ($C_{22}H_{23}NO_4$) [365.43]	Buparvaquone	2-*trans*(4-*t*-butylcyclohexyl)methyl-3-hydroxy-1,4-naphthoquinone ($C_{21}H_{26}O_3$) [326.44]	Parvaquone	2-cyclohexyl-3-hydroxy-1,4-naphthoquinone ($C_{16}H_{16}O_3$) [256.30]	Atovaquone	2-[*trans*-4-(4-chlorophenyl)cyclohexyl]-3-hydroxy-1,4-naphthoquinone ($C_{22}H_{19}ClO_3$) [366.69]	
Figure 42.6 Hydroxyquinolones and naphthoquinones.

from the intestinal tract, and what is absorbed is rapidly cleared from the blood and tissues and is only minimally excreted in the milk (Quintero de Leonardo et al., 2008). Evidence indicates that decoquinate can have an anticoccidial effect on first-generation schizonts of *E. tenella*, adversely affect sporulation, and permit the development of immunity if fed at levels that are lower than its coccidiostatic levels (Williams, 1997). This anticoccidial effect also leads to improved feed efficiency and milk production. Activity against *Toxoplasma* and *Cryptosporidium* has also been demonstrated in cattle and sheep.

Decoquinate is licensed and marketed in multiple countries worldwide, including the US, Latin America, Europe, and the Middle East (Taylor and Bartram, 2012). There is some variation between countries in the indications for use and the target species. Formulations in the United States are approved for chickens, calves, beef cattle, and nonlactating dairy cattle, either as a monotherapy, or combined with other drugs including chlortetracycline, lincomycin, tylan, or monensin. Since extralabel use of feed additives is prohibited by the FDA, use in other species in the US is not allowed in this manner.

Clinical Use

Chickens: Decoquinate is used for prevention of coccidiosis caused by *Eimeria* sp. in broilers. It should be fed for at least 28 days when development of coccidiosis is likely. Do not feed to laying chickens. No withdrawal is required.

Cattle: In cattle, decoquinate is used to prevent coccidiosis caused by *Eimeria* sp. when fed for at least 28 days. In beef cattle, no withdrawal time is required. For treatment of cryptosporidiosis, doses of 2 mg/kg were not effective at decreasing oocyst shedding or clinical signs in experimentally challenged calves (Moore et al., 2003). However, treatment of pregnant cows with 1.25 mg/kg/day in the feed for 30 days prior to and for 8 days after parturition prevented clinical signs in the calves.

Sheep: Decoquinate is fed to sheep to provide 0.5 mg/kg BW for at least 28 days to prevent coccidiosis. It is also effective as an aid in the prevention of abortions and perinatal losses due to toxoplasmosis when fed at a dosage of 2 mg/kg BW daily, starting 14 weeks prior to lambing.

Goats: Decoquinate is fed to goats to provide 0.5 mg/kg BW for at least 28 days to prevent coccidiosis. It also reduces clinical cryptosporidiosis in goats fed medicated milk replacer.

Dogs: For preventing clinical relapses of *Hepatozoon americanum* infection, decoquinate feed additive (27.2 grams decoquinate per pound of premix) can be added to moist dog food at a rate of 0.5–1.0 tablespoons per 10 kg BW twice a day (Macintire et al., 2001). Decoquinate has been shown to be effective in resolving clinical signs of infection in a dog diagnosed with severe myositis associated with *Sarcocystis* sp. infection where the drug was used at a dose of 10–20 mg/kg BW orally twice a day (Sykes et al., 2011).

Horses: Decoquinate has been used for the treatment of equine protozoal myeloencephalitis (EPM) caused by *Sarcocystis neurona* at a dose of 0.5 mg/kg orally once daily, combined with levamisole (1 mg/kg) for 10 days total. Improvement in clinical signs with this combination has been noted (Ellison and Lindsay, 2012) and in vitro testing has shown decoquinate to have a cidal effect on developing shizonts of *S. neurona* at concentrations of 240 nM (Lindsay et al., 2013). There are no commercially available, approved combination products and studies have used compounded drug. Further information is necessary before this treatment can be recommended.

Atovaquone

Atovaquone (Mepron® suspension) is a hydroxyquinolone that has broad-spectrum antiprotozoal activity. It is a yellow crystalline solid that is practically insoluble in water. Atovaquone is supplied as a bright yellow suspension of microfine particles at a concentration of 150 mg atovaquone/ml. It is highly lipophilic and administering it with food increases its absorption twofold. It was originally developed for human use to treat drug-resistant strains of malaria and *Pneumocystis carinii* pneumonia. It is discussed here because it was also found to have excellent activity against *T. gondii* and *Babesia* sp. It also has activity against *Eimeria* spp. Atovaquone is thought also to work via inhibition of electron transport at the mitochondrial bc1 complex because cross-resistance often develops between atovaquone and decoquinate (Pfefferkorn et al., 1993).

Clinical Use

Dogs: Atovaquone in combination with azithromycin is the treatment of choice for canine babesiosis (Birkenheuer, 2014). It was administered (13.3 mg/kg PO q 8 h) concurrently with azithromycin (10 mg/kg PO q 24 h) for 10 consecutive days and was shown to completely eliminate *Babesia gibsoni* infection from 8 of 10 dogs treated (Birkenheuer et al., 2004). The dogs in that study had previously been treated unsuccessfully with imidocarb or diminazene. Decreased susceptibility of *B. gibsoni* to treatment with atovaquone in some dogs is associated with a single nucleotide polymorphism in the *B. gibsoni* mitochondrial cytochrome b gene sequence (Matsuu et al., 2006).

Cats: In cats diagnosed with *Cytauxzoon felis*, atovaquone (15 mg/kg PO q 8 h) administered concurrently with azithromycin (10 mg/kg PO q 24 h) for a duration of 10 days was shown to significantly increase survival compared to cats treated with imidocarb dipropionate (3.5 mg/kg given intramuscularly once and then repeated 7 days later) (Cohn et al., 2011).

Parvaquone and Buparvaquone

Parvaquone (Clexon®) and buparvaquone (Butalex®) are naphthoquinones that are used for the treatment of theileriosis. They act on the macroschizonts and intraerythrocytic piroplasms.

Theileriosis is a severe disease of cattle in Africa and is caused by *Theileria parva*, a piroplasm. Several *Theileria* spp. infect wild ruminants in the United States, but none of these causes serious illness.

Clinical Use

Cattle: Parvaquone is administered IM at 20 mg/kg BW as a single treatment for theileriosis. Buparvaquone is given IM at 2.5 mg/kg BW for one or two treatments. Both drugs are considered curative for *Theileria* infections in cattle (Muraguri et al., 1999).

Cats: Parvaquone and buparvaquone have been used to treat *Cytauxzoon felis* infections in cats, although their efficacy is questionable (Kier, 1990).

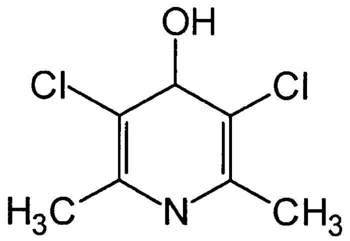
Pyridinols

Spectrum: Coccidiosis, *Leucocytozoon* sp.

Drugs included: Clopidol (Figure 42.7).

Clopidol

Clopidol (Coyden 25®) is the only pyridinol to be used as an anticoccidial. It is practically insoluble in water. It is active against the sporozoite stage, allowing host cell penetration but not parasite development. It also has activity against second-generation schizogony, gametogony, and sporulation. Sporozoites can resume development after the medication is removed. Little anticoccidial immunity develops in chickens receiving this agent. Long (1993) suggested that the mode of action of clopidol was similar to that of the quinolone anticoccidials because of similar structure and biological activity of the agents. However, cross-resistance between clopidol and quinolone anticoccidials does not occur (Long, 1993).



Clopidol

($C_7H_7Cl_2NO$)

[192.06]

Figure 42.7

Clinical Use

Chickens and turkeys: Clopidol is fed at 0.0125–0.025% for prevention of coccidiosis. A 5-day withdrawal is required if the 0.025% level is used. This level may be lowered to 0.0125% 5 days before withdrawal. Clopidol is transmitted to the eggs of hens that are fed clopidol-containing diets (Long, 1971). Clopidol is also approved for the prevention of *Leucocytozoon smithi* infections in turkeys when fed at its anticoccidial levels.

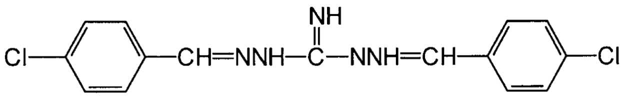
Guanidine Derivatives

Spectrum: Coccidiosis.

Drugs included: Robenidine (Figure 42.8).

Robenidine

Robenidine (Cycostat®, Robenz®) is a synthetic anticoccidial derivative of guanidine. It is active against the first-generation schizont of *E. tenella* by preventing formation of merozoites. Feeds with robenidine should not be given to laying hens, as studies have shown that robenidine is transmitted to the eggs (Long et al., 1981), and these eggs may have an unpleasant taste even though the ability of humans to taste robenidine is apparently under genetic



Robenidine

($C_{15}H_{13}Cl_2N_5$)

[334.21]

Figure 42.8

control. It does not have any other adverse effects on egg production or quality.

Clinical Use

Chickens: Robenidine is used for the prevention of coccidiosis in chickens. Finish feeds must be fed within 50 days of manufacture. Addition of bentonite clays to feeds may decrease the activity of robenidine. A 5-day withdrawal is required. If robenidine is not withdrawn 5 days before slaughter, the flesh of medicated birds will have an unpleasant taste.

Rabbits: Robenidine can be used for the prevention of coccidiosis caused by *Eimeria* sp. in rabbits when fed at 0.75–1.00 kg per ton of complete feed to supply 50–66 ppm robenidine hydrochloride. Use at these feed levels carries a 5-day withdrawal time.

Thiamine Analogues

Spectrum: Coccidiosis.

Drugs included: Amprolium (Figure 42.9).

Amprolium

Amprolium (Corid®, Amprol®) is approved for use in the United States as a preventative and treatment of *Eimeria* infections in chickens, turkeys, pheasants, and calves. It is one of the most commonly administered anticoccidial agents in veterinary medicine. It is structurally related to vitamin B_1 (thiamine) and the antiparasitic activity of the drug is thought to be related to competitive inhibition of active thiamine transport into the parasite. There is a 50-fold greater sensitivity of the parasite system compared with the host system. However, long-term or high-dose administration of amprolium can lead to clinical thiamine deficiency in treated animals, resulting in cerebrocortical necrosis (polioencephalomalacia).

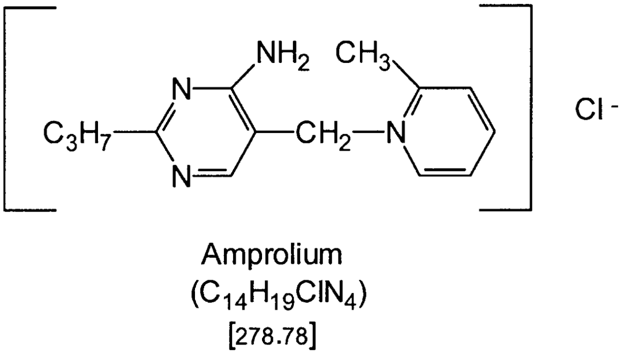


Figure 42.9

Amprolium is freely soluble in water. Because amprolium lacks the hydroxyethyl function of thiamine it is not phosphorylated to a pyrophosphate analog (Looker et al., 1986). Amprolium acts on the first-generation schizont to prevent merozoite production and has some activity against sexual stages and the sporulating oocyst. Amprolium-resistant strains of chicken and turkey *Eimeria* spp. are prevalent, therefore it is often combined with other agents to increase activity.

Clinical Use

Chickens and turkeys: Amprolium is used for the prevention of coccidiosis in chickens as a feed additive or in the drinking water. No withdrawal is required. Amprolium is used for the treatment and prevention of coccidiosis in turkeys when fed continuously.

Pheasants: Amprolium is approved for use in the prevention of coccidiosis in pheasants and is fed continuously. It must not be used in feeds containing bentonite.

Cattle: Amprolium is given to calves in the feed, drinking water, or orally at 5 mg/kg BW for 21 days to prevent coccidiosis or at 10 mg/kg BW for 5 days as an aid to treat coccidiosis.

Goats: Amprolium is used for the treatment of pathogenic *Eimeria* sp. in goats. Resistance is common and increasing, therefore higher doses are recommended. Doses of 50 mg/kg orally once daily for 5 days effectively reduced shedding of oocysts whereas 10 mg/kg did not (Young et al., 2011).

Dogs: In dogs, amprolium can be used for the treatment of coccidiosis at 100–200 mg total dose (20% powder) orally once a day for 7–12 days. Amprolium is also used in the drinking water (sole source) at 30 ml (9.6% solution)/gal for up to 10 days or in the food at 250–300 mg (20% powder) once a day for 7–12 days.

Cats: Amprolium can be used for the treatment of coccidiosis at 110–220 mg/kg orally once a day for 7–12 days. Amprolium is also used in the drinking water (sole source) at 1.5 teaspoons (9.6% solution)/gal for up to 10 days. Amprolium can be combined with sulfadimethoxine and used for the treatment of coccidiosis at 150 mg/kg BW amprolium and 25 mg/kg BW sulfadimethoxine once a day for 14 days.

Nitrobenzamides

Spectrum: Coccidiosis.

Name	Chemical name (Empirical formula) [Molecular weight]	Chemical structure
Aklomide	2-chloro-4-nitrobenzamide ($C_7H_5ClN_2O_3$) [200.60]	Dinitolmide	2-methyl-3,5-dinitrobenzamide ($C_8H_7N_3O_5$) [225.16]	
Figure 42.10 Nitrobenzamides.

Drugs included: Aklomide, dinitolmide (Figure 42.10).

Aklomide and Dinitolmide

Aklomide and dinitolmide (Zoamix®) are nitrobenzamide anticoccidial agents. These agents act primarily on the first-generation schizonts, and dinitolmide inhibits sporulation of oocysts (Mathis and McDougald, 1981). Dinitolmide is coccidiostatic if given for 6 days but is coccidiocidal if given for longer periods (Long, 1993). Nitrobenzamide-resistant strains of coccidia are common. The anticoccidial mode of action of nitrobenzamides is not known.

Aklomide is not currently marketed as a single agent or combined with other anticoccidial drugs in the United States.

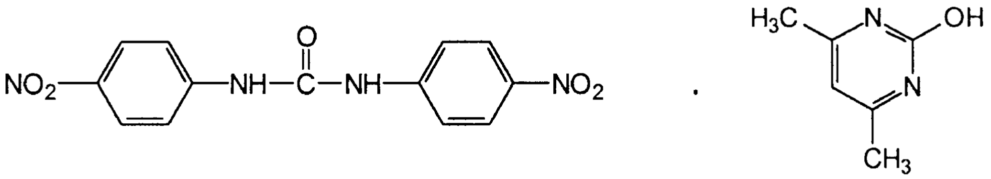
Clinical Use

Chickens and turkeys: Dinitolmide is fed as a single agent to prevent coccidiosis in chickens. Do not feed to layers or birds over 14 weeks of age. Dinitolmide is also approved for use in nonlaying turkeys in feed in birds up to 14–16 weeks of age. Combination products are also available.

Nicarbazin

Spectrum: Coccidiosis.

Nicarbazin (Nicarb®, Cycarb®) is an equimolecular complex of 4,4′-dinitrocarbanilide and 2-hydroxy-4,6-dimethylpyrimidine (Figure 42.11). The agents are absorbed separately from the digestive tract, and both are needed for anticoccidial activity. Dry crystals are strongly electrostatic and present some dry-mixing problems. The precise mode of action of nicarbazin is not known. Nicarbazin causes reduced egg production, depressed egg weight, and reduced eggshell thickness and egg-yolk mottling when fed to white leghorn layers at 125 ppm (Jones et al., 1990). It also causes poor hatchability and depigmentation of brown-shelled eggs. Nicarbazin is usually restricted in use to the starting period because of potential growth-suppressing effects and to cooler months of the year because of its potential to enhance the effects of heat distress (McDougald, 1993).



Nicarbazin
($C_{19}H_{18}N_6O_6$)
[426.38]

Figure 42.11

Clinical Use

Chickens: Nicarbazin is fed for the prevention, but not the treatment, of coccidiosis. It is not labeled for laying hens. A combination of narasin and nicarbazin (Maxiban®) is available for prevention of coccidiosis in broilers. It is for broilers only and should not be fed to other types of chickens. The use of this combination has been associated with increased mortality of broilers in times of heat distress. Feed containing this combination may cause fatalities in horses that ingest it, and it should not be fed to adult turkeys.

Alkaloids

Spectrum: Coccidiosis, theileriosis.

Drugs included: Halofuginone (Figure 42.12).

Halofuginone

Halofuginone (Stenerol®) is an alkaloid originally isolated from the plant *Dichroa febrifuga*. Halofuginone is active against the asexual stages of coccidia. Its anticoccidial mode of action is not known. Halofuginone is transmitted to eggs from hens that have been fed halofuginone for 1 week (Long et al., 1981), but no adverse effects on egg production or egg quality have been associated with administration (Jones et al., 1990). Halofuginone has been associated with skin tears in chickens, and it has been shown to be an inhibitor of collagen type I synthesis in avian and mammalian cells (Granot et al., 1993). Halofuginone is toxic to fish and other aquatic life and must not be fed to waterfowl. Halofuginone is a skin and eye irritant and appropriate precautions (such as protective clothing) should be taken when handling this agent.

Clinical Use

Chickens and turkeys: Halofuginone is used for the prevention of coccidiosis in chickens when administered in feed. Do not feed to layers. Halofuginone is also approved for the prevention of coccidiosis in growing turkeys.

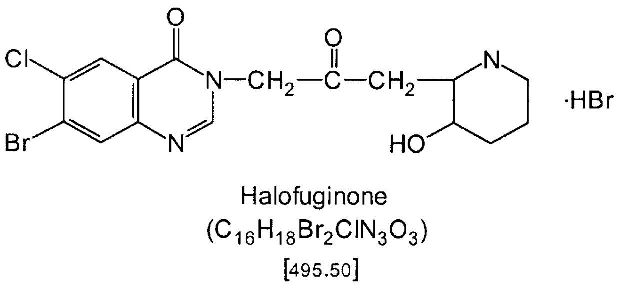


Figure 42.12

Cattle: In cattle, halofuginone is given orally at 1–2 mg/kg BW for a single treatment and is curative for *Theileria* infections. At 2 mg/kg BW transient diarrhea may occur. Halofuginone is given orally at 100 μg/kg BW orally once a day for 7 days as a treatment or preventative for *Cryptosporidium* spp. infections in calves. While some studies indicate that lower numbers of oocysts and decreased severity of diarrhea can be observed in treated calves, others have identified no clinical benefit (Trotz-Williams et al., 2011; Klein, 2008). The utility of halofuginone is likely influenced by multiple factors. Halofuginone is more effective at reducing clinical disease and decreasing shedding of *Cryptosporidium* in calves when calves are housed individually (De Waele et al., 2010) and when no other concurrent infections are present (Meganck et al., 2015).

Polyether Ionophores

Spectrum: Coccidiosis.

Drugs included: Lasalocid, maduramicin, monensin, narasin, semduramicin, salinomycin (Figure 42.13).

The polyether ionophore antibiotics were first discovered in the early 1950s, and their anticoccidial activities were recognized in the late 1960s. Because of their broad spectrum of activity and the development of drug resistance to other agents, the ionophores gained widespread usage in the poultry industry soon after their introduction. Polyether ionophores fall into one of five classes: monovalent, monovalent glycosides, divalent, divalent glycosides, or divalent pyrrole ethers. The mode of action of ionophores is related to their ability to form lipophilic complexes with alkali metal cations and to transport these cations across biological membranes. Different ionophores may produce varying affinities for different cations. Ionophores that have anticoccidial activity are thought to act against extracellular sporozoites and merozoites. Extracellular stages develop membrane blebs indicating alterations in membrane integrity and in internal osmolality. Because coccidia have no osmoregulatory organelles, this change in internal osmotic conditions damages the parasites.

Because of the unique mode of action of ionophores, development of anticoccidial resistance to ionophores was difficult to produce under experimental conditions and slow to develop after clinical use in the field. In the mid to late 1980s, ionophore-resistant strains of chicken *Eimeria* spp. were documented in the United States, and ionophore resistance is now common. Cross-resistance between ionophores is common, although strain differences in coccidial response to specific ionophores have been demonstrated. In general, resistance to a monovalent polyether ionophore confers some cross-resistance

Name	Chemical name (Empirical formula) [Molecular weight]	Chemical structure
Lasalocid	6-[7*R*-[5*S*-Ethyl-5-(5*R*-ethyltetra-hydro-5-hydroxy-6 *S*-methyl-2*H*-pyran-2*R*-yl) tetrahydro-3*S*-methyl-2*S*-furanyl]-4*S*-hydroxy-3*R*,5*S*-dimethyl-6-oxonon-yl]-2-hydroxy-3-methylbenzoic acid $(C_{34}H_{54}O_8)$ [590.80]	Maduramicin	(3*R*,4*S*,5*S*,6*R*,7*S*,22*S*)-23,27-Didemethoxy-2,6,22-tridemethyl-11-*O*-demethyl-22-[(2,6-dideoxy-3,4-di-*O*-methyl-β-Larabinohexopyranosyl)oxy]-6-methyloxylonomycin A monoammonium salt $(C_{47}H_{83}NO_{17})$ [934.17]	Monensin	2-[5-Ethyltetrahydro-5-[tetrahydro-3-methyl-5-[tetrahydro-6-hydroxy-6-(hydromethyl)-3,5-dimethyl-2*H* -pyran-2-yl]-2-furyl]-2-furyl]-9-hydroxy-β-methoxy-α, γ, 2,8-tetramethyl-1,6-dioxaspiro [4.5] decane-7-butyric acid $(C_{36}H_{62}O_{11})$ [670.90]	Narasin	(αβ,2β,3α,5α,6α)-α-ethyl-6-[5-[5-(5α-ethyltetrahydro-5β-hydroxy-6α-methyl-2*H*-pyran-2β-yl)-3″α,4,4″,5,5″α,6″-hexahydro-3′β-hydroxy-3″β,5α,5″β-trimethylspiro] furan-2(3*H*),2′-[2*H*]pyran-6′(3′*H*),2″-[2*H*]pyran]6″α-yl]2α-hydroxy-1α,3β-dimethyl-4-oxoheptyl]-tetrahydro-3,5-dimethyl-2*H*-pyran-2-acetic acid $(C_{43}H_{72}O_{11})$ [765.05]	Semduramicin	(2*R*,3*S*,4*S*,5*R*,6*S*)-tetrahydro-2,4-dihydroxy-6-[(1*R*)-1-[(2*S*,5*R*,7*S*,8*R*,9*S*)-9-hydroxy-2,8-dimethyl-2-[(2*R*,6*S*)-tetrahydro-5-methyl-5-[(2*R*,3*S*,5*R*)-tetrahydro-5[(2*S*,3*S*,5*R*,6*S*)-tetrahydro-6-hydroxy-3,5,6-trimethyl-2*H*-pyran-2-yl]-3-[[(2*S*,5*S*,6*R*)-tetrahydro-5-methoxy-6-methyl-2*H*-pyran-2- yl]oxy]-2-furyl]-2-furyl]-1,6-dioxaspirol [4.5]dec-7-yl]ethyl]-5-methoxy-3-methyl-2*H*-pyran-2-acetic acid $(C_{44}H_{77}O_{16})$ [748.47]	
Figure 42.13 Ionophores antibiotics.

to other monovalent polyether ionophores, but susceptibility to monovalent monoglycoside and divalent polyether ionophores may be retained.

Ionophores are potentially toxic for highly susceptible species. Horses appear to be the most sensitive species, with a monensin LD_{50} of 1.4 mg/kg, compared with goats (LD_{50} 26.4 mg/kg) and chickens (LD_{50} 214 mg/kg) (Deljou et al., 2014). Clinical signs occur from acute myocardial and muscle degeneration. Sweating, colic, and ataxia with hindlimb paresis/paralysis are also noted. Pathologically, focal degenerative cardiomyopathy, skeletal muscle necrosis, and congestive heart failure may be noted. Ionophore toxicosis can be potentiated with concurrent administration of tiamulin, chloramphenicol, macrolides, sulfonamides, and cardiac glycosides (Novilla, 1992; Mitema et al., 1988). Exposure of horses to ionophores is usually accidental, or resulting from horses gaining access to medicated feed, particularly through feed mill errors. Care should always be taken to prevent highly susceptible animals from gaining access to feeds containing these products.

Lasalocid

Lasalocid (Avatec®, Bovatec®) is a divalent polyether ionophore that is a fermentation product of *Streptomyces* *lasaliensis* and was the second ionophore marketed in the United States. Lasalocid is well tolerated when fed with tiamulin (Meingasser et al., 1979). Lasalocid is transmitted to eggs of hens that have been fed this medication for 1 week.

Clinical Use

Chickens and turkeys: Lasalocid is fed for the prevention of coccidiosis in chickens. Lasalocid is also approved for the prevention of coccidiosis in growing turkeys.

Chukar partridges: Lasalocid is approved for the prevention of coccidiosis in chukar partridges and is fed until the birds are 8 weeks old.

Cattle: In cattle, lasalocid is used to prevent coccidiosis and is fed at 1 mg/kg BW, with a maximum of 360 mg/animal/day. Do not use in breeding animals.

Sheep: Lasalocid is fed in the ration to sheep to provide 15–70 mg/animal/day and is used in the prevention of coccidiosis. Do not administer to breeding animals.

Rabbits: Lasalocid is approved for use in the prevention of hepatic coccidiosis in rabbits and is fed until the rabbits are 6.5 weeks old.

Maduramicin

Maduramicin (Cygro®) is a monovalent monoglycoside polyether ionophore that is a fermentation product of *Actinomadura yumaense*. Maduramicin does not adversely affect egg production or egg quality (Jones et al., 1990). Maduramicin is well tolerated when fed with tiamulin (Meingasser et al., 1979). At higher doses (≥6 ppm), an adverse effect on growth and feathering may occur.

Clinical Use

Chickens: Maduramicin is used for the prevention of coccidiosis in broilers and fed at 5 ppm. It is for broilers only and should not be fed to other types of chickens.

Monensin

Monensin (Coban®, Rumensin®) is a monovalent polyether ionophore that is a fermentation product of *Streptomyces cinnamonensis*. Tiamulin may interfere with the metabolism of monensin in chickens and cause weight suppression (Meingasser et al., 1979). Monensin is apparently not transmitted to eggs of hens fed monensin for 1 week, nor does it adversely affect egg production or quality. Mature turkeys and guinea fowl should not have access to monensin-containing diets. Monensin will cause deaths in horses and guinea fowl that ingest feeds containing it.

Clinical Use

Chickens and turkeys: Monensin is fed for prevention of coccidiosis in broilers. Do not feed to layers or chickens over 16 weeks of age. Monensin is used for prevention of coccidiosis in turkeys. Do not feed to turkeys over 10 weeks old.

Bobwhite quail: Monensin is approved for use in bobwhite quail for prevention of coccidiosis and is fed at 73 g/ton from 1 day to 10 weeks old.

Cattle: In cattle, monensin is used to prevent coccidiosis and is fed to provide 100–360 mg/animal/day. It has recently been approved for use in dairy cattle as well, with a zero meat and milk withdrawal time.

Goats: Monensin is fed at 20 g/ton for the prevention of coccidiosis in confinement-reared goats. Do not feed to goats producing milk for human consumption.

Narasin

Narasin (Monteban®) is a monovalent polyether ionophore that is a fermentation product of *Streptomyces aureofaciens*. It is structurally similar to salinomycin, differing only in the presence of a methyl group in narasin that is not present in salinomycin. It does not adversely affect egg production or egg quality. Narasin may cause fatalities in horses that ingest it, and it should not be fed to adult turkeys. Tiamulin may interfere with the metabolism of narasin in chickens and cause weight suppression (Meingasser et al., 1979).

Clinical Use

Chickens: Narasin is a feed additive for the prevention of coccidiosis in broilers. It is for broilers only and should not be fed to other types of chickens.

Semduramicin

Semduramicin (Aviax®) is a monovalent monoglycoside polyether ionophore that is a fermentation product of a mutant of *Actinomadura roseorufa* (Ricketts et al., 1992). The parent produced a diglycoside form of semduramicin that had to be semisynthetically modified. Both forms of the monoglycoside agent have identical activity. It is well tolerated when coadministered with tiamulin (Ricketts et al., 1992).

Clinical Use

Chickens: Semduramicin is used as a feed additive for prevention of coccidiosis in broiler chickens.

Salinomycin

Salinomycin (Bio-Cox®) is a monovalent polyether ionophore that is a fermentation product of *Streptomyces albus* and was the third ionophore marketed in the United States. Salinomycin is active against sporozoites and early and late asexual stages of chicken coccidia (Conway et al., 1993). Salinomycin does not adversely affect egg production or egg quality. Tiamulin may interfere with the metabolism of salinomycin in chickens and cause weight suppression (Meingasser et al., 1979). It is not for use with pellet binders such as bentonite clays. Salinomycin will cause deaths in horses and adult turkeys that ingest feeds containing it. Toxicity associated with salinomycin in horses and cats has been related to predominately neurological signs, although elevations in muscle enzymes are often present (Aleman et al., 2007; Pakozdy et al., 2010).

Clinical Use

Chickens: Salinomycin is fed for prevention of coccidiosis in broilers. Do not feed to layers.

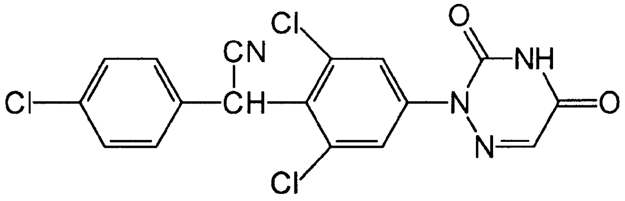
Bobwhite quail: Salinomycin is approved for prevention of coccidiosis in bobwhite quail when administered in feed.

Triazine Derivatives

Spectrum: *Sarcocystis neurona*, coccidiosis, toxoplasmosis, *Neospora caninum*, *Neospora hughesii*.

Drugs included: Diclazuril, toltrazuril, ponazuril (Figures 42.14, 42.15). The triazine antiprotozoal drugs act on the apicoplast, a plastid obtained by endosymbiosis that is present in apicomplexan parasites, but is not present in the vertebrate host. The exact function of the apicoplast is not known; however, it may play a vital role in biosynthesis of amino acids and fatty acids, assimilation of nitrate and sulfate, and starch storage, as has been demonstrated for other plastid organelles (Kühler et al., 1997; Fichera and Roos, 1997).

Diclazuril



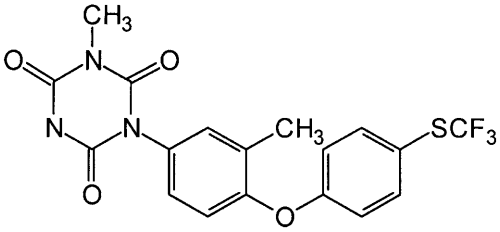
Diclazuril
($C_{17}H_9Cl_3N_4O_2$)
[407.64]

Figure 42.14

Diclazuril (Clinicox®, Protazil®) is a benzeneacetonitrile that has potent anticoccidial activity when fed at low levels in the feed. The mechanism of action against *Sarcocystis neurona* is to inhibit merozoite production.

Clinical Use

Horses: Diclazuril has been used as a treatment for equine protozoal myeloencephalitis (EPM). Doses of 5 mg/kg (equivalent to 500 grams Clinicox®/ 450-kg horse) have been successful in improving clinical signs of EPM using a shorter duration of treatment (30 days) compared to therapy with combinations of sulfonamides and pyrimethamine (90–120 days). However, because of the large volume of drug to be administered, some horses have to be given the drug via a nasogastric tube, which makes treatment inconvenient and difficult. Approval of an alfalfa-based pelleted formulation (Protazil™, 1.56%) has made treatment with diclazuril in horses much more practical because it can be added as a top-dressing to feed for repeated dosing. The pharmacokinetics have been well defined in horses (Dirikolu et al., 1999; Hunyadi et al., 2015; Hunyadi L, Papich MG, Pusterla N, unpublished data). In the study by Dirikolu et al. (1999) after a dose of 2.5 grams per 450 kg (as Clinacox®) it had a half-life of approximately 43 hours and maintained concentrations at 7–9 µg/ml with daily doses for 21 days. Cerebrospinal fluid (CSF) concentrations were



Toltrazuril
($C_{18}H_{14}F_3N_3O_4S$)
[425.38]

Figure 42.15

approximately 15% of plasma concentrations. Concentrations believed to be required to inhibit *Sarcocystis neurona* are 1 ng/ml. In more recent studies (Hunyadi et al., 2015; Hunyadi L, Papich MG, Pusterla N, unpublished data) the pelleted medication designed for top-dressing horse feed (Protazil$^{\mathrm{TM}}$, 1.56%) was administered to horses at the approved dose of 1 mg/kg and at a lower dose of 0.5 mg/kg. The half-life was approximately 87 and 55 hours from the low and high dose, respectively. After multiple doses to steady-state once daily, the half-life was 72 hours and 54 hours from the low and high dose, respectively, and the plasma drug concentrations were not different between the low dose and high dose. CSF concentrations were 5.7% of the plasma concentrations at the low dose. Because of the long half-life, and no difference between 0.5 mg/kg and 1.0 mg/kg, a follow-up study was performed in which it was shown that a dosing schedule of every 3 or 4 days of 0.5 mg/kg of the pelleted formulation would maintain concentrations above the desired threshold in horses to inhibit *Sarcocystis* (Hunyadi L, Papich MG, Pusterla N, unpublished data).

Chickens: Diclazuril is approved for use in broilers as a preventative for coccidiosis. There are several other combination products available as well. The withdrawal times can vary, depending on the product. This drug is not approved for use in laying hens.

Turkeys: Diclazuril is approved for use in the prevention of coccidiosis in turkeys. It is also available combined with bacitracin. These products should not be fed to breeding turkeys or layers.

Rabbits: When fed at 1–2 ppm continuously in pelleted feed, diclazuril was effective in controlling the clinical signs of intestinal coccidiosis in experimentally infected rabbits (Vanparijs et al., 1989).

Toltrazuril

Toltrazuril (Baycox®, Procox®) is a triazinon drug that has broad-spectrum anticoccidial and antiprotozoal activity. It is not commercially available in the United States, but it is available in other countries. It is active against both asexual and sexual stages of coccidia by inhibiting nuclear division of schizonts and microgamonts and the wall-forming bodies of macrogamonts. It may also be useful in the treatment of neonatal porcine coccidiosis, EPM, and canine hepatozoonosis.

Clinical Use

Swine: Toltrazuril has been shown to reduce the signs of coccidiosis in naturally infected nursing pigs when a single oral 20–30 mg/kg BW dose is given to 3 to 6-day-old pigs (Driesen et al., 1995). Clinical signs were reduced from 71 to 22% of nursing pigs, and diarrhea and oocyst excretion were also decreased by the single oral treatment. Approved products carry a 77-day withdrawal time in the United Kingdom.

Calves and lambs: Toltrazuril is used for the prevention of clinical signs of coccidiosis and reduction of coccidia shedding in calves and lambs as a single dose treatment. Withdrawal times in the United Kingdom are 63 and 42 days for calves and lambs, respectively.

Dogs: For hepatozoonosis, toltrazuril given orally at 5 mg/kg BW every 12 hours for 5 days or given orally at 10 mg/kg BW every 12 hours for 10 days caused remission of clinical signs in naturally infected dogs in 2–3 days (Macintire et al., 2001). Unfortunately, most treated dogs relapsed and eventually died from hepatozoonosis. In puppies with *Isospora* sp. infection, treatment with 0.45 mg emodepside in combination with 9 mg/kg BW toltrazuril (Procox®, Bayer Animal Health) reduces fecal oocyst count by 91.5–100%. There was no difference in duration of diarrhea when treatment was begun after the onset of clinical signs during patent infection (Altreuther et al., 2011).

Cats: In kittens experimentally infected with *Isospora* spp., treatment with a single oral dose of 0.9 mg emodepside in combination with 18 mg/kg BW toltrazuril (Procox®, Bayer Animal Health) reduces oocyst shedding by 96.7–100% if given during the prepatent period (Petry et al., 2011).

Horses: Toltrazuril has also been used for the treatment of EPM. This drug is safe, even at high doses. Current recommended treatments are 5–10 mg/kg orally for 28 days. Despite the favorable efficacy with toltrazuril, its use has diminished in horses because of better availability of other effective drugs.

Ponazuril

Ponazuril (Marquis®), also known as toltrazuril sulfone, is an active metabolite of toltrazuril; therefore, its mechanism of action is identical to that of toltrazuril. It is available in a paste formulation for horses. It has activity against *Sarcocystis neurona, Toxoplasma gondii, Isospora suis*, and *Neospora caninum.*

Clinical Use

Horses: Ponazuril is approved for use in horses as a treatment for EPM at a dose of 5 mg/kg orally for 28 days. Treatment can be extended for another 28 days if no improvement is seen. A loading dose of 15 mg/kg orally once is recommended to attain therapeutic plasma and CSF concentrations for *S. neurona* after a single dose. Successful treatment of EPM caused by *N. hughesii* with ponazuril has also been described (Finno et al., 2007). No adverse effects have been noted. Intermittent administration of ponazuril at 20 mg/kg orally once a week has been recommended as a preventative dosing for EPM, as it significantly decreased intrathecal anti-*S. neurona* antibody responses in horses inoculated with *S. neurona* sporocysts (MacKay et al., 2008).

Cattle: Ponazuril has been shown to be effective at a dose of 20 mg/kg orally once a day for 6 days in calves experimentally infected with *Neospora caninum*.

Swine: There are no approved ponazuril products for use in swine; however, the equine formulation has good oral bioavailability in swine and is used extralabel for treatment of coccidiosis caused by *Isospora suis*. Unlike the other triazine drugs, ponazuril is cidal against all intracellular and developmental stages of *Isospora* and it does not interfere with natural immunity (Mehlhorn et al., 1984). A single oral dose of 5 mg/kg to 2 to 3-month-old piglets resulted in a half-life of 5.6 days and detectable plasma concentrations for at least 33 days (Zou et al., 2014). This, coupled with the lack of tissue residue data, mean that any animal treated with ponazuril would require a greatly prolonged withdrawal time.

Dogs and cats: Ponazuril at a dose of 50 mg/kg BW orally once a day for 3 days decreases excretion of *Cystoisospora* spp. oocysts below the detection limit in 92.9% and 87.5% of treated shelter dogs and cats, respectively. Animals with high fecal oocyst counts were significantly more likely to remain infected and to require a second treatment course (Litster et al., 2014).

Sulfonamides

Spectrum: Coccidiosis.

Drugs included: Sulfaguanidine, sulfadiazine, sulfadimethoxine, sulfadoxine, sulfamethazine (syn. sulfadimidine), sulfamethoxazole, sulfanitran, and sulfaquinoxaline (Figure 42.16).

Sulfonamides were the first effective anticoccidials used. Sulfonamides can be either coccidiostatic or coccidiocidal. The pharmacology of sulfonamides is also discussed in Chapter 32. The structure of sulfonamides is similar to para-aminobenzoate (para-aminobenzoic acid, PABA), which is required by bacteria in the synthesis of folate (folic acid). Sulfonamides interfere in the early phases of folate synthesis. Mammalian and avian cells use preformed folate and are therefore not affected by the sulfonamide treatments. Sulfonamides are often used in combination with dihydrofolate reductase/thymidylate synthase (DHFR/TS) inhibitors such as trimethoprim, pyrimethamine, or ormetoprim, because of the observed synergistic effects due to activity at two places in folate biosynthesis. Sulfonamides have most activity against the asexual stages and lesser activity against the sexual stages of coccidia.

Sulfonamides used in veterinary medicine for the treatment or prevention of coccidia and coccidia-like parasites include sulfaguanidine, sulfadiazine, sulfadimethoxine, sulfadoxine, sulfamethazine (in some countries called *sulfadimidine*), sulfamethoxazole, sulfanitran, and sulfaquinoxaline. Many are used in combination with other products that have antibacterial or growth-promoting properties. Combinations with trimethoprim or ormetoprim are discussed in Section Dihydrofolate Reductase/Thymidylate Synthase Inhibitors.

Clinical Use

Chickens and turkeys: Sulfamethazine is approved for use in chickens and turkeys for the treatment of coccidiosis when administered in drinking water. Sulfamethazine should not be administered to animals producing eggs for human consumption.

Cattle: Sulfamethazine is used to treat coccidiosis in calves by oral administration of a single dose of 100 mg of sulfamethazine per pound of body weight the first day and 50 mg per pound of body weight on each following day, not to exceed 5 days. Other formulations are also available. Do not feed to preruminating calves or lactating dairy cattle. Sulfaquinoxaline can be administered in the drinking water for 3 to 5 days. Treated animals must actually consume enough medicated water to provide 6 mg per pound body weight per day. Do not feed to calves to be slaughtered under 1 month old or use in lactating dairy cattle. Extralabel use of sulfonamides in adult dairy cattle is prohibited by the FDA.

Dogs and cats: Several agents have been used for the treatment of intestinal coccidiosis in dogs and cats (Lindsay et al., 1997a), but only sulfadimethoxine is approved by the FDA for this usage. Sulfadimethoxine is used for treatment of coccidiosis in dogs and cats at 55 mg/kg BW for 1 day, and then 27.5 mg/kg BW once a day for 14–20 days.

Rabbits: Sulfaquinoxaline is used in the feed of rabbits for 30 days for treatment of coccidiosis.

Name	Chemical name (Empirical formula) [Molecular weight]	Chemical structure
Sulfadiazine	4-amino-*N*-2-pyrimidinylbenzenesulfonamide ($C_{10}H_{10}N_4O_2S$) [250.28]	Sulfadimethoxine	4-amino-*N*-(2,6-dimethoxy-4-pyrimidinyl)-benzenesulfonamide ($C_{12}H_{14}N_4O_4S$) [310.33]	Sulfadoxine	4-amino-*N*-(5,6-dimethoxy-4-pyrimidinyl)-benzenesulfonamide ($C_{12}H_{14}N_4O_4S$) [310.34]	Sulfaguanidine	4-amino-*N*-(aminoiminomethyl)-benzenesulfonamide ($C_7H_{10}N_4O_2S$) [214.24]	Sulfamethazine	4-amino-*N*-(4,6-dimethyl-2-pyrimidinyl)-benzenesulfonamide ($C_{12}H_{14}N_4O_2S$) [278.32]	Sulfamethoxazole	4-amino-*N*-(5-methyl-3-isoxazolyl)-benzenesulfonamide ($C_{10}H_{11}N_3O_3S$) [253.31]	Sulfaquinoxaline	4-amino-*N*-2-quinoxalinyl-benzenesulfonamide ($C_{14}H_{12}N_4O_2S$) [300.33]	Sulfanitran	4′-[(*p*-nitrophenyl)sulfamoyl]acetanilide ($C_{14}H_{13}N_3O_5S$) [335.34]

Dihydrofolate Reductase/Thymidylate Synthase Inhibitors

Spectrum: Coccidiosis, *Toxoplasma* sp., *Neospora* sp., *S. neurona*, leucocytozoon, *Hepatozoon americanum*.

Drugs included: trimethoprim, ormetoprim, pyrimethamine (Daraprim) (Figure 42.17).

In protozoa, unlike other eukaryotic cells, the dihydrofolate reductase and thymidylate synthase enzymes do not exist as separate molecular entities, but instead these enzymes are part of a bifunctional DHFR/TS complex that has both DHFR and TS activity (Roos, 1993). The best known and most often used members of this group are trimethoprim, ormetoprim, and pyrimethamine. These drugs were previously introduced in Chapter 32.

Trimethoprim

Trimethoprim is available in several formulations, as well as in trimethoprim combinations for oral or parenteral administration. Examples include trimethoprim + sulfadiazine (Tribrissen®, Di-Trim®) and trimethoprim + sulfamethoxazole (Bactrim®, Septra®, human drugs). Trimethoprim also is available as a single drug

Name	Chemical name (Empirical formula) [Molecular weight]	Chemical structure
Trimethoprim	2,4-diamino-5-(3,4,5-trimethoxybenzyl)pyrimidine ($C_{14}H_{18}N_4O_3$) [290.32]	Pyrimethamine	2,4-diamino-5-(*p*-chlorophenyl)-6-ethylpyrimidine ($C_{12}H_{13}ClN_4$) [248.71]	Diaveridine	2,4-diamino-5-veratrylpyrimidine ($C_{13}H_{16}N_4O_2$) [260.29]	Ormetoprim	2,4-diamino-5-(4,5-dimethoxy-2-methylbenzyl)-pyrimidine ($C_{13}H_{15}N_4O_2$) [259.17]	
Figure 42.17 Dihydrofolate reductase/thymidylate synthase inhibitors.

(Proloprim). Pharmacology of trimethoprim is discussed in more detail in Chapter 32.

Trimethoprim is readily absorbed from the digestive tract after oral administration, and peak serum levels occur 1–4 hours later. The half-life is 3.8 hours in the horse, 3.0 hours in the dog, and 10.6 hours in human beings. Concurrent administration of a sulfonamide does not affect the rate of absorption of trimethoprim. Trimethoprim is widely distributed in tissues. Concentrations of trimethoprim in cerebral spinal fluid are about 40% of those in the serum (Zinner and Mayer, 1990). Trimethoprim is almost completely (60–80%) excreted by the kidneys within 24 hours, and some is also excreted in the bile. The remainder is excreted as metabolites by the kidneys. Use of trimethoprim and other DHFR/TS inhibitors is associated with adverse effects on bone marrow. Administration of folinic acid usually will counteract these adverse effects.

Trimethoprim is available in several tablet, liquid, and paste formulations in combination with sulfamethoxazole (Cotrimethoxazole®, Bactrim®, Septra®) or sulfadiazine (Di-Trim®) that are usually in the ratio of 1 part trimethoprim to 5 parts sulfonamide. In addition to their antibacterial use (Chapter 32), these agents are used in treatment of coccidiosis, toxoplasmosis, neosporosis, EPM, and malaria. Adverse reactions to these agents are similar to those of the individual constituents. Adverse effects from the sulfonamide are more common, but adverse effects from trimethoprim are also possible. These combinations should not be used in animals with liver disease, blood dyscrasias, or a history of sulfonamide sensitivity. Precautions normally observed when animals are taking sulfonamides should be observed. The safety of ormetoprim–sulfadimethoxine has not been established in pregnant dogs, but studies indicate that the use of trimethoprim–sulfadiazine is safe in pregnant dogs. Trimethoprim–sulfonamides have caused thyroid disorders in piglets from treated sows. Trimethoprim is not absorbed following oral administration in ruminating animals.

Clinical Use

Dogs: Sulfadiazine combined with trimethoprim is used as a treatment for coccidiosis at 5–10 mg/kg BW trimethoprim combined with 25–50 mg/kg BW of sulfadiazine, given for 6 days to dogs over 4 kg BW. Dogs under 4 kg BW are given half this dosage for 6 days. Remission of clinical signs of hepatozoonosis can be obtained by oral administration of a combination of trimethoprim–sulfadiazine (15 mg/kg BW every 12 hours), clindamycin (10 mg/kg every 8 hours), and pyrimethamine (0.25 mg/kg every 12 hours) for 14 days (MacIntire et al., 2001). As the therapy is ineffective in eliminating the tissue stages of the organism, clinical response is short lived. Clinical relapses may be prevented by subsequent therapy with decoquinate (MacIntire et al., 2001).

Cats: Agents and dosages used for the treatment of canine coccidiosis are also used for the treatment of feline coccidiosis.

Ormetoprim

Ormetoprim combined with sulfadimethoxine (Rofenaid 40®) is the only combination DHFR/TS-sulfonamide presently available in the United States for poultry. Other combinations are intended for use in human beings, equines, and small animals. Ormetoprim is also available in combination with sulfadimethoxine in the ratio of 1 part ormetoprim plus 5 parts sulfadimethoxine (Primor®) in various size tablets.

Clinical Use

Chickens and turkeys: Combinations are fed to chickens at 0.0075% ormetoprim and 0.0125% sulfadimethoxine to prevent coccidiosis in broiler chickens. Do not feed to birds producing eggs for food. Ormetoprim combined with sulfadimethoxine is fed to turkeys at 0.00375% ormetoprim and 0.00625% sulfadimethoxine to prevent coccidiosis. Do not feed to birds producing eggs for food.

Dogs: Sulfadimethoxine combined with ormetoprim is used as a treatment for coccidiosis in dogs at 11 mg/kg BW ormetoprim plus 55 mg/kg BW sulfadimethoxine for up to 23 days.

Pyrimethamine

The advantage of pyrimethamine is that it has much greater affinity for the dihydrofolate reductase enzyme of protozoa than bacteria (Ferone et al., 1969). The inhibitory activity against protozoal dihydrofolate reductase was 140 times greater for pyrimethamine than trimethoprim; but by contrast, the activity against the bacterial enzyme was 500 times less for pyrimethamine than trimethoprim. Activity against mammalian blood cells is also greater for pyrimethamine, making this agent more prone to cause folate-deficient anemia in animals.

Pyrimethamine is available in 25-mg tablets. Pyrimethamine is well absorbed after oral administration and is slowly but extensively metabolized. Less than 3% is excreted in the urine in the first 24 hours, and the half-life is 4–6 days in human beings (Van Reken and Pearson, 1990). It accumulates in the kidneys, lungs, liver, and spleen. It is excreted in urine as metabolites, but some pyrimethamine can be found in the milk. Very high doses of pyrimethamine are teratogenic in laboratory animals. Pyrimethamine is available in tablets that contain 25 mg pyrimethamine and 500 mg sulfadoxine (Fansidar®), and in tablets that contain 12.5 mg pyrimethamine and 100 mg dapsone (Maloprim®). The equine formulation is a suspension (ReBalance®) that contains pyrimethamine (12.5 mg/ml) + sulfadiazine (250 mg/ml).

Clinical Use

Avian: Pyrimethamine (1 ppm) combined with sulfadimethoxine (10 ppm) will prevent but not cure *Leucocytozoon caulleryi* infections in birds.

Dogs and cats: For toxoplasmosis, cats and dogs are treated orally with 0.25–0.5 mg/kg BW pyrimethamine and 30 mg/kg BW sulfonamide (preferably, sulfadiazine) every 12 hours for 2–4 weeks. Canine neosporosis will also respond to the above regimens of DHFR/TS inhibitors and sulfonamides used to treat canine toxoplasmosis. Bone marrow suppression can occur with the synergistic use of pyrimethamine and sulfonamides and can be corrected by the addition of folinic acid (5 mg/day) or by the addition of yeast (100 mg/kg BW daily) to the animal's diet.

Horses: Treatment recommendations for equine protozoal myelitis include sulfadiazine at 20–30 mg/kg BW orally twice daily combined with oral pyrimethamine at 1 mg/kg BW once daily for 30 days after clinical signs have stopped improving. Twelve weeks is the average length of treatment time. Relapse is possible if horses are not treated long enough, and reactivation of the infection may occur during periods of unusual stress. This treatment has fallen out of favor, because of the length of treatment required; however, it provides a less expensive alternative compared to other treatments. The presence of food may adversely affect the absorption of DHFR/TS inhibitors, and food should be withheld 1–2 hours before and after treatment. Cell culture studies have shown that pyrimethamine kills developing *S. neurona* at 1.0 μg/ml and trimethoprim kills it at 5.0 μg/ml (Lindsay and Dubey, 1999). These levels of agent probably are not reached in the treated horses. It has been suggested that intermittent (every 2 or 4 weeks) single EPM treatment may help prevent clinical relapse in horses recovering from EPM (MacKay et al., 1992). If relapse does occur, the entire treatment regimen should be repeated. A study of 12 horses with EPM on a farm with an EPM outbreak indicated that combination treatment with trimethoprim–sulfonamides and pyrimethamine resulted in transient fever, anorexia, and depression in two; acute worsening of ataxia in two; mild anemia in four; and abortions in three (Fenger et al., 1997). Prolonged use of DHFR/TS inhibitors has long been known to result in bone marrow suppression. Therefore, horses should be examined periodically (about every 2 weeks) for anemia and leukopenia. If the neutrophil counts drop below 3000 cells/μl, treatment should be discontinued until the counts recover (MacKay et al., 1992). Caution should be used when treating pregnant mares with this combination of drugs, as congenital defects, including skin lesions, bone marrow aplasia, and renal dysplasia, have been reported (Toribio et al., 1998). This occurred despite folic acid supplementation to the mares during treatment. Folinic acid, not folic acid, is recommended for treatment of folate deficiency; however, it may reduce the efficacy of the DHFR/TS inhibitor as some protozoal species are able to utilize folinic acid (Piercy et al., 2002).

Lincosamides

Spectrum: Toxoplasmosis, *Neospora* sp., hepatozoonosis.

Drugs included: Clindamycin, Lincomycin (Figure 42.18).

Clindamycin

Clindamycin (Antirobe®, Cleocin®) has been used for treatment of disseminated toxoplasmosis in cats and dogs (Lindsay et al., 1997b). The pharmacology of lincosamides, including clindamycin, is discussed in more detail in Chapter 36. It is a semisynthetic compound produced by alteration of the parent molecule lincomycin, which is produced by *Streptomyces lincolnensis*. It differs from lincomycin in having a chlorine group at C-7 rather than a hydroxyl group. The dosages used against *T. gondii* are higher than for the treatment of the aerobic and anaerobic bacteria for which it has an approved indication. Clindamycin is active against tachyzoites of *Toxoplasma gondii* and is initially coccidiostatic but becomes coccidiocidal after a few days of treatment. Oral and parenteral formulations of clindamycin have similar activity. The drug is almost completely absorbed after oral administration in both dogs and cats, and peak serum concentrations occur within 75 minutes (Harari and Lincoln, 1989). The half-life is about 5 hours after oral or IV administration. Clindamycin is widely distributed in many tissues and fluids and crosses the placenta and blood–brain barrier. It is metabolized in the liver and excreted in the bile and urine as parent agent and metabolites.

Clinical Use

Dogs and cats: For toxoplasmosis, cats are treated with clindamycin at 10–12 mg/kg BW orally every 12 hours for 4 weeks or treated with 12.5–25 mg/kg BW clindamycin IM every 12 hours for 4 weeks.

Dogs are treated with 3–13 mg/kg BW orally or IM every 8 hours for 2 weeks or with 10–20 mg/kg BW orally or IM every 12 hours for 2 weeks. Clindamycin is also combined with pyrimethamine and used for the treatment of toxoplasmic encephalitis in human beings;

Name	Chemical name (Empirical formula) [Molecular weight]	Chemical structure
Clindamycin	(2*S*-*trans*)-methyl-7-chloro-6,7,8-trideoxy-6-[[(1-methyl-4-propyl-2-pyrrolidinyl)carbonyl]-amino]-1-thio-L-threo-α-D-galacto-octopyranoside ($C_{18}H_{33}ClN_2O_5S$) [424.98]	Lincomycin methyl	6,8-dideoxy-6-[[(-1-methyl-4-propyl-2-pyrrolidinyl)carbonyl]amino]-1-thio-D-erythro-α-D-galacto-octopyranoside ($C_{18}H_{34}N_2O_6S$) [406.56]	
Figure 42.18 Lincosamides.

such combinations might have applications in veterinary medicine. Neonatal canine neosporosis is treated with 12.5–18.5 mg/kg BW clindamycin orally twice daily for 2–4 weeks (Dubey and Lindsay, 1998). Death may be prevented in pups with severe hindlimb involvement, but hindlimb function usually does not return to normal. The amount of clinical improvement will depend on the degree of paralysis that has occurred.

The response of *H. americanum*–infected dogs to treatment with a combination of trimethoprim plus sulfadiazine (orally 15 mg/kg BW every 12 hours) plus clindamycin (orally 10 mg/kg BW every 8 hours) plus pyrimethamine (orally 0.25 mg/kg BW daily) (TCP therapy) for 14 days demonstrated that remission of clinical signs in naturally infected dogs occurred in 2–3 days, but most treated dogs relapsed and eventually died from hepatozoonosis (Macintire et al., 2001). The best results have been seen in dogs that have undergone TCP therapy and then been placed on a daily oral treatment program with 10–20 mg/kg BW decoquinate. The decoquinate treatment must be continued because once it is stopped, relapse and clinical disease occur (Macintire et al., 2001). Dogs have tolerated this treatment and survived for over 18 months.

Azalides

Spectrum: Cryptosporidiosis, toxoplasmosis, babesiosis, cytauxzoonosis.

Drugs included: Azithromycin (Zithromax®).

The azalide antimicrobials are derivatives of the macrolides. The pharmacology of the macrolides is discussed in more detail in Chapter 36. They have activity against bacteria, as well as mycoplasma and have been investigated for the treatment of cryptosporidiosis in human patients with HIV infection, with some success (Kadappu et al., 2002). In vitro activity against *Toxoplasma gondii* has also been demonstrated. Azalides exhibit their antibacterial activity through inhibition of protein synthesis by binding to the 50S ribosomal unit of susceptible bacteria. The antiprotozoal mechanism of action is unknown.

Azithromycin

Azithromycin differs from other azalides and the macrolides by having a much higher volume of distribution and by its ability to accumulate within phagocytic cells. Concentrations are 100–200 times higher in neutrophils than in the plasma (Davis et al., 2002). The clinical effectiveness has been attributed to the high concentrations in cells and some tissues. However, it also has other immunomodulatory effects and may improve patients by exerting therapeutic benefits not completely explained by the antimicrobial activities (Parnham et al., 2014).

Clinical Use

Cattle: Azithromycin dihydrate given to calves naturally infected with cryptosporidiosis under field conditions, at doses of 1500 or 2000 mg per day, had a lower incidence of diarrhea, decreased oocyst shedding, and increased weight gains (Elitok et al., 2005; Nasir et al., 2013). The recommended treatment regimen is 1500 mg/calf/day for 7 days.

Dogs: Azithromycin (10 mg/kg PO q 24 h) administered concurrently with atovaquone (13.3 mg/kg PO q 8 h) for 10 consecutive days was shown to completely eliminate *Babesia gibsoni* infection from 8 of 10 dogs treated (Birkenheuer et al., 2004). The dogs in that study had previously been treated unsuccessfully with imidocarb or diminazene.

Cats: In cats diagnosed with *Cytauxzoon felis*, atovaquone (15 mg/kg PO q 8 h) administered concurrently with azithromycin (10 mg/kg PO q 24 h) for a duration of 10 days was shown to significantly increase survival compared to cats treated with imidocarb dipropionate (3.5 mg/kg given IM once and then repeated 7 days later) (Cohn et al., 2011).

4-Aminoquinolines

Spectrum: *Plasmodium* sp.

Drugs included: Chloroquine.

Chloroquine

Chloroquine has been used in the treatment of avian malaria. The mechanism of action against malarial organisms involves concentration of the drug, which is a weak base, within the acidic food vacuoles of the parasites. Once inside the cell, chloroquine causes rapid clumping of heme pigments by inhibiting plasmodial heme polymerase activity (Slater and Cerami, 1992). Heme then accumulates to toxic levels, causing cell death.

Clinical Use

Penguins: Clinical malaria in penguins that are kept in zoos or aquariums is caused by *Plasmodium relictum*. It is treated with an oral loading dose of 10 mg/kg BW chloroquine, followed by oral doses of 5 mg/kg BW given 6, 18, and 24 hours later (Clubb, 1986).

Diamidine Derivatives

Spectrum: Piroplasmosis, *Hepatozoon canis.*

Drugs included: *Aromatic derivatives:* diminazene diaceturate, pentamidine isethionate, phenamidine isethionate. *Carbanilide derivatives:* amicarbalide, imidocarb dipropionate (Figure 42.19).

These diamidine derivatives bind to DNA and interfere with parasite replication (Pilch et al., 1995; Patrick et al., 1997). This class of drugs has a tendency to accumulate in tissues; therefore, half-lives are very long, which may lead to residue problems in food-producing animals. Imidocarb was still detectable in liver samples from treated cattle 224 days after drug administration (Coldham et al., 1994). Specific drugs have been shown to cross the placenta, as well as the blood–brain barrier. Toxicity may involve renal disease, hepatic disease, or pulmonary congestion and edema, and is dose dependent. Treatment of babesiosis may produce clinical cures in some animals, but the infection is not completely cleared, leading to a carrier state in affected individuals. This depends on the susceptibility of the organism being treated.

Diminazene Diaceturate

Diminazene diaceturate (Berenil®, Ganaseg®) has a very long half-life, which is reported to be up to 29 days in the plasma of cattle, with the highest concentrations in tissues being found in the kidneys (Mdachi et al., 1995). Diminazene is excreted into the milk, with residues being reported for up to 6 days in sheep and goats (el Banna et al., 1999), and up to 21 days in cattle (Mdachi et al., 1995). Parasitic infections can alter the pharmacokinetics of this drug.

Clinical Use

Horses: *Babesia caballi* infections can be treated with 3–5 mg/kg BW IM, but 6–12 mg/kg BW is required for *B. equi* in horses. Doses as low as 0.5 mg/kg BW can be effective against *B. bigemina*. Diminazene at 5.0 mg/kg BW will eliminate *B. caballi* from horses if given twice during a 24-hour period (Kuttler, 1988).

Cattle: Diminazene at a dose of 3–5 mg/kg IM is effective against *B. bigemina* and *B. bovis* infections (Vial and Gorenflot, 2006). Doses of 3.5–7 mg/kg IM have been used for treatment of trypanosomiasis.

Dogs: A single 3.5–5 mg/kg BW IM treatment with diminazene is effective against canine babesiosis caused by *Babesia canis*, but 3.5 mg/kg BW given twice over 24 hours is required for *B. gibsoni*. The drug may enable survival against acute hemolytic crises and clinical improvement, but is inconsistent in clearing infection. Higher cumulative doses may produce central nervous system signs.

Name	Chemical name (Empirical formula) [Molecular weight]	Chemical structure
Amicarbalide	3,3′-(Carbonyldiimino)*bis*-benzenecarboximidamide ($C_{15}H_{16}N_6O$) [296.34]	Diminazene	*N*-acetylglycine compounded with 4,4′-(1-triazene-1,3-diyl) *bis*-(benzenecarboximidamide) ($C_{22}H_{29}N_9O_6$) [515.54]	Imidocarb	3,3′-di-2-imidazolin-2-yl-carbanilide ($C_{19}H_{20}N_6O$) [348.41]	Pentamidine	4,4′-[1,5-pentanediylbis(oxy)] *bis*benzenecarboximidamide ($C_{19}H_{24}N_4O_2$) [340.43]	Phenamidine	4,4′-oxybisbenzenecarboximidamide ($C_{14}H_{14}N_4O$) [254.29]	
Figure 42.19 Diamidine derivatives.

Cats: For treatment of *Cytauxzoon* infection, two injections are given intramuscularly at 2 mg/kg BW within a 1-week interval (Greene et al., 1999). Diminazene is ineffective for elimination of the carrier state of *Cytauxzoon* infection in cats (Lewis et al., 2014). Diminazene is not effective against *B. felis* but is effective against *B. herpailuri* in cats.

Pentamidine Isethionate

Pentamidine isethionate (Lomidine®, Pentam 300®) is useful in programs that are attempting to produce immunity in cattle by abbreviating infections.

Clinical Use

Cattle: When given SC during the acute phase at 0.5–2 mg/kg BW, pentamidine usually produces a clinical cure, but as much as 5 mg/kg BW will not completely eradicate the parasite from cattle.

Dogs: Pentamidine is effective against canine babesiosis when given IM at 16.5 mg/kg BW on 2 consecutive days but may cause adverse reactions, including pain at the injection site, hypotension, tachycardia, and vomiting. It has also been used in the treatment of leishmaniais at a dose of 4 mg/kg BW IM twice weekly for 4 weeks. This regimen was repeated again 3 weeks later. Clinical remission was obtained in all dogs treated, and signs did not appear during a 6-month follow-up period (Noli and Auxilia, 2005). Pentamidine isethionate given at 4 mg/kg BW intramuscularly at days 14, 16, 18, 20, 22, 24, and 26 following experimental infection constituted a safe and efficient trypanocide in *T. brucei brucei* infected dogs (Akpa et al., 2008).

Phenamidine Isethionate

Phenamidine isethionate (Lomadine®) can be used to treat bovine and equine *Babesia* infections with 8–13 mg/kg BW IM. Phenamidine at 8.8 mg/kg BW will eliminate *B. caballi* from horses if given twice during a 24-hour period (Kuttler, 1988).

Dogs: Phenamidine isethionate given SC at 15–20 mg/kg BW once a day for 2 days, is effective against canine babesiosis caused by *B. gibsoni*; a single dose of 8–13 mg/kg is effective against *Babesia canis*.

Amicarbalide

Amicarbalide (Diampron®) is effective against bovine babesiosis when given IM at 5–10 mg/kg BW. Amicarbalide at 8.8 mg/kg BW will eliminate *B. caballi* from horses if given twice during a 24-hour period but will not eliminate *B. equi* when used at levels of 22 mg/kg BW, which approaches toxic levels (Kuttler, 1988).

Imidocarb Dipropionate

Imidocarb diproprionate (Imizol®) is one of the treatments of choice for babesial infections. Also, administration of imidocarb may interfere with the efficacy of some babesial vaccines in certain species (Combrink et al., 2002). In cattle, the elimination half-life of imidocarb in liver was 48.5 days and 120 days in muscle (Coldham et al., 1995). A dose-dependent hepatic toxicity has been noted.

Clinical Use

Cattle: Imidocarb is effective against bovine babesiosis when given at 1–3 mg/kg BW IM or SC.

Horses: Imidocarb given at 1–2 mg/kg BW will eliminate *B. caballi* from horses if given twice during a 24-hour period (Kuttler, 1988). When given at 4 mg/kg IM every 72 hours for a total of four doses, imidocarb produced a significant increase in the urine γ-glutamyl transferase (GGT) : creatinine ratio, as well as mild azotemia in normal horses (Meyer et al., 2005). Liver function was not affected. This dose has been shown to be ineffective in eliminating the carrier state in *B. equi*–infected animals (Kuttler et al., 1987). At higher doses (16 and 32 mg/kg BW), renal failure, hepatic failure, and pulmonary edema were noted (Adams, 1981). When administered to pregnant mares, imidocarb was detectable in fetal blood at levels similar to those found in the dam's blood (Lewis et al., 1999). Imidocarb is also used in the treatment of *Theileria equi*; however, sensitivity varies up to fourfold depending on the strain (Hines et al., 2015) and may explain why some animals fail to completely clear the organism.

Dogs: A single 7.5 mg/kg BW SC imidocarb treatment will completely clear *Babesia canis* infections in dogs (Penzhorn et al., 1995). A single dose of 3.5 mg/kg BW SC diminazene, followed the next day by a single dose of 6 mg/kg BW SC imidocarb, will completely clear *Babesia canis* infections in dogs (Penzhorn et al., 1995). To eliminate *Babesia canis*, the recommendation when using imidocarb alone is 6.6 mg/kg IM or SC, and repeat in 14 days (Birkenheuer, 2014). Although imidocarb is not considered a first choice against *Babesia gibsoni* infections in dogs, it has produced clinical improvement (Birkenheuer, 2014). *Hepatozoon canis* infections are treated with 5–6 mg/kg BW SQ or IM every 2 weeks until gamonts are no longer present in blood smears (Baneth and Weigler, 1997). Complete elimination of *H. canis* with this protocol may frequently not be achievable (Sasanelli et al., 2010).

Cats: For treatment of *Cytauxzoon* infection, two injections are given intramuscularly at 3.5 to 5 mg/kg BW within a 1–2 week interval (Greene et al., 1999; Cohn et al., 2011). Control of parasympathetic side effects is recommended by pretreating cats with atropine or glycopyrrolate. Feline babesiosis is refractory to treatment with imidocarb.

Nitrothiazole Derivatives

Spectrum: *Giardia, Coccidia, cryptosporidiosis, S. neurona*

Drugs included: Nitazoxanide.

The antiprotozoal action of the nitrothiazole derivatives is thought to be via interference with the pyruvate-ferredoxin oxidoreductase enzyme dependent electron transfer reaction, which is essential for anaerobic energy metabolism of the parasites (Parashar and Arya, 2005). It is specific for parasites capable of intracellular reduction of the nitro group on the drug to a toxic-free radical. Nitazoxanide (NTZ) is rapidly converted to an active metabolite, deacetylnitazoxanide (also known as tizoxanide), in the horse (Navigator Paste, package insert), as well as in humans (Parashar and Arya, 2005).

Nitazoxanide

Nitazoxanide (Navigator®) was available as a 32% paste to treat equine protozoal myeloencephalitis (EPM). The adverse effects in horses are numerous and can be severe, including a fatal enterocolitis at recommended doses; therefore it was voluntarily withdrawn from the market by the sponsor. In vitro and in vivo efficacy against *Cryptosporidium* organisms has also been demonstrated (Jenkins, 2004). It is approved by the FDA as a treatment for cryptosporidial infection in children (Alinia®).

Clinical Use

Horses: Field trials with NTZ have shown a success rate, defined by an improvement in neurological signs and/or conversion to a negative result on western blot of the CSF, of 57–81%. This included a 78% success rate for horses that had previously been treated with other drugs for EPM. Horses are treated for 28 days. For the first 5 days, the dose is 11.36 mg/lb (25 mg/kg) orally once daily. The dose is then increased to 22.72 mg/lb (50 mg/kg) orally once daily for the remaining 23 days. This drug should not be used in horses less than 1 year of age or in those horses that have concurrent disease.

Cattle: Nitazoxanide was shown to reduce the duration of shedding of *Cryptosporidium parvum* oocysts and the severity of diarrhea in experimentally infected calves. For treatment of cryptosporidiosis, calves were orally administered 1.5 grams NTZ suspended in water twice a day (Ollivett et al., 2009).

Cats: Sustained inhibition of *Cryptosporidium* oocyst shedding in the feces of four naturally infected cats after a single oral dose of 75 mg/kg BW has been reported. However, reshedding of oocysts was prompted by administration of corticosteroids. NTZ is not well tolerated by cats and results in vomiting and dark, foul-smelling diarrhea (Gookin et al., 2001).

Ectoparasiticides

Ronald E. Baynes

Introduction

The focus of this chapter is to describe the pharmacology of veterinary drugs and pesticides currently approved to control important ectoparasites that adversely affect domestic animal health and production. These ectoparasites are primarily insects (fleas, flies, lice) and ascarines (ticks and mites). Effective control of these ectoparasites is not only critically important for the veterinary patients, but also from a public health perspective as several of the animal ectoparasites not only transmit disease between animals but they can also transmit major diseases to humans. Fleas are known vectors for tapeworms, *Diplidium caninum,* and humans can develop cat scratch disease when *Bartonella henselae* is transmitted from cats to humans via cat fleas. Flea allergy dermatitis is major concern for companion animals. These are amongst the most important reasons why flea control in companion animals is critical, and explains why annual expenditures to control fleas have totaled in excess of $2.0 Billion in the USA and Western Europe (Kramer and Mencke, 2001). Ticks can transmit Lyme disease, Rocky Mountain spotted fever, babesia in dogs and cattle, and heartwater in ruminants, to mention only a few. Mosquitoes can transmit West Nile virus to humans and heartworm diseases to pets, malaria to birds, rodents, and primates, and they also serve as biological vectors of viral encephalitides in horses. Flies not only transmit disease and cause damage to hides and coat of pets, their nuisance can result in decreased feed intake in livestock and thus reduced timely weight gain, resulting in economic loss to livestock farmers. Face flies are known to transmit the causative agent (*Moraxella bovis*) of pink eye or infectious bovine keratoconjunctivitis in cattle. Control of myiasis-causing flies can be significantly improved with effective ectoparasiticides.

The *feeding behavior* of ectoparasites differ and this may be critical if the drug of choice is strictly a repellent or adulticide. Adult fleas usually engorge themselves with a blood meal from the host with 5 minutes to 1 hour of infestation of the animal, with female fleas feeding for about 25 minute and males feeding for 11 minutes (Cadiergues et al., 2000). In order to prevent flea allergy dermatitis, an effective ectoparasiticide should be able to prevent this feeding behavior. Comparative efficacy studies suggest that organophosphates (OPs) and/or pyrethroids are more effective than the newer ectoparasiticides in preventing the flea from taking the first blood meal (Franc and Cadiergues, 1998). Ticks feed on a blood meal for a longer period (days) before it is completed. Under these conditions pathogens such as *Borrelia burgdorferi,* which causes Lyme disease, become well adapted to this long feeding period. However, with other tick-borne pathogens, such as *Ehrlica* and *Rickettsia*, transmission can occur within the first hours. For these reasons, the use of combination drugs (insecticide and repellent) will prevent ticks from attaching and feeding (Young et al., 2003). A good example of this desired combined efficacy is a drug formulation containing the repellent permethrin and the acaricide imidacloprid.

The ideal ectoparasiticide should not only be an effective repellent and adulticide, it must also be *persistent* in the blood or skin surface at therapeutic concentrations for a significantly long time, such as 1–3 months, so that there is adequate client compliance. Another challenge is that the formulation of an insecticide must be *stable* to sunlight and also water/shampooing. An excellent example of this is imidacloprid, which is photostable and persistent after shampooing compared to the early generation pyrethroids that were not very stable in sunlight. Some formulations, such as Frontline Plus®, contain the adulticide (fipronil) as well as an insect growth inhibitor (methoprene), because by the time pets are observed to be infested with fleas, the fleas would already have laid eggs. A final consideration in choice of therapy is whether to *treat the environment* as well as the animal. There appears to be a new paradigm within the last 10 years of treating the pet and not the environment (Rust, 2005).

Pharmaceutics of Topical Formulations

Many of the commercial topical ectoparasiticides used to treat domestic animals are formulated to be released from (i) liquid organic/aqueous formulations and/or (ii) synthetic polymers such as collars and ear tags. The rate of penetration through the skin or translocation across the skin surface is dependent on several critical pharmaceutical properties. Liquid formulations include pour-ons, topical sprays, and dips, which consist of the active ingredient and other (formerly called inert) ingredients that can modulate dermal pharmacokinetics. These other ingredients include mostly alcohols, oils, and spreading agents (Magnusson et al., 2001). The ear tags are composed of a solid organic polymeric macromolecule (e.g., polyvinyl chloride) and an active ingredient that are mixed with the tag and formed by injection molding. These devices are designed to slowly release the insecticide over a defined time period (e.g., Cutter Gold® last 5 months) as the animal moves its head, but it should be removed at the end of the fly season or before slaughter.

Transdermal Delivery

Topical application is the more common for administration of ectoparasiticides. An understanding of the dermal pharmacokinetics of these drug and pesticide formulations will further the understanding of drug efficacy and safety. The fundamentals of this topic are covered in Chapter 47. Many of these drugs and pesticides are very lipophilic with large molecular weights, and therefore it is not surprising that there is slow dermal absorption and low systemic *bioavailability*, as well as a large volume of distribution and long plasma and tissue half-lives. All of these are important factors when considering repeat applications and strategies to minimize the emergence of pest resistance, whether it is in a house, kennel, or pasture, and also to minimize drug residues in food-producing animals.

The advantages of transdermal delivery include ease of application to the animal's coat and it avoids the problems of first-pass metabolism and also the gastrointestinal degradation often associated with oral administration. Some of the major disadvantages associated with this route of administration are pet owners sometimes overdose the animal with topical sprays or pour-on formulations, which often result in toxicoses in sensitive populations such as feline species and juveniles. Licking is part of the natural grooming and social behavior of many animal species, which can result in significant oral absorption and subsequently increased systemic exposure in the treated and also untreated animals that are part of a large livestock herd (Laffont et al., 2003). Application of pour-on products to food animals can result in significantly longer withdrawal times when compared to administration by oral or injection routes. This is most evident with ivermectin pour-on products, which cause significant retention of ivermectin in the skin layers and thus prolong release of the drug. For example, this results in a 45-day withdrawal time for the pour-on product versus 35 days for the subcutaneous route (KuKanich et al., 2005).

Routes of Dermal Absorption

There are five possible routes (Figure 43.1) for a drug or pesticide to diffuse as it partitions from the formulation on the skin surface through the stratum corneum and viable epidermis before entering the microcapillaries at the epidermal–dermal juncture. Many, if not all, of the ectoparasiticides diffuse through the intercellular matrix (intercellular route) in the stratum corneum and viable epidermis. This matrix may vary biochemically between animal species, but in all species it consist of varying proportions of fatty acids, ceramides, and cholesterol. The reader should also be aware that apparent epidermal thickness (Monteiro-Riviere et al., 1990) varies across animal species in the following order, thereby influencing the intercellular path length for the diffusing pesticide:

Porcine	>	**Cattle**	>	**Canine**	>	**Feline**
(52 µm)		(37 µm)		(21 µm)		(13 µm)

The intracellular route and sweat pores are less likely routes for these lipophilic chemicals as they have more hydrophilic properties than the intercellular matrix.

Even though light microscopy examination of skin suggest that the hair follicle extends into the dermis and hypodermis, this is not really true. The hair follicle is

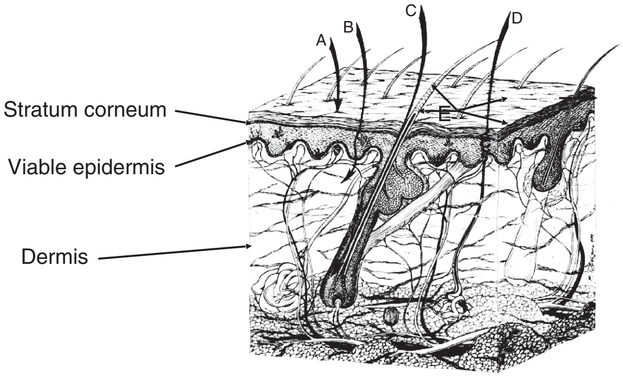

Figure 43.1 Pathways for drug and insecticide transport in mammalian skin. A, transcellular; B, intercellular; C, transfollicular; D, sweat pore; E, lateral diffusion.

really a deep invagination of the epidermis, and therefore if a drug travels down the hair follicle, it still has to cross the epidermis in order to gain access to the circulatory system. However, the presence of many hair follicles significantly increases the effective epidermal surface area, and thus increased flux, although the apparent surface area may be the same. This in part explains why care must be taken when administering pour-on ectoparasiticides in an extralabel manner across species. In essence, hair follicles and are arranged and distributed differently across animal species, and these differences can dictate transdermal delivery into the systemic circulation for pour-on products as well as translocation across the skin surface for topicals. The coat may contain primary and or secondary hair follicles. The former are large diameter and deep rooted into the dermis and associated with sebaceous and sweat glands. The secondary follicles are smaller in diameter, they are near the surface, and have sebaceous glands, but no sweat gland erector pili muscle. Horses and cattle have single hair follicles distributed evenly while pigs have single follicles grouped in clusters of four follicles. Dogs have primary and secondary follicles with as many as 15 hairs emerge from a single opening in the skin. Goats have primary follicles in groups of three, with three to six secondary follicles associated with each group. Sheep are bit more complex. They have hair-growing regions with mostly single follicles on face, distal legs region, and ears, and they have wool growing regions over most of their body, which can be defined as mostly compound follicles. A cluster will have three primary follicles and several secondary follicles.

Mechanisms of Action

Structures of many of the compounds to be discussed in this chapter are depicted in Table 43.1. Ectoparasiticides can have the following broad mechanisms of action that can affect the biology of the ectoparasite. More specific examples are summarized in Table 43.2.

- Ectoparasite nervous system
  - acetylcholinesterase (AChE) inhibitors
  - Na^+ channel blockers
  - nicotinic acetylcholine receptor (nAChR) inhibitors
  - γ amino butyric acid (GABA)/glutamate receptor Cl^- channel inhibitors
- Ectoparasite repellant
- Insect growth and development.

A good ectoparasiticide has a high efficacy against the ectoparasite and is not toxic to the host. Many of the OP and organochlorine pesticides are very effective and have a broad spectrum activity. However, because of their toxicity to mammals (Table 43.2), there are safer pesticides available for veterinary use, and fewer chemicals from these two classes are being used in veterinary medicine. For this reason, this chapter will not discuss the organochlorines especially as they are no longer approved for veterinary use. The newer ectoparasiticides such as the neonicotinoids (e.g., imidacloprid) are more selective for certain insects such as fleas, and very few other insects. However, the term broad spectrum may be misleading. Recall that ivermectin, which is often regarded as a broad-spectrum antiparasitic drug, is indeed highly effective against many nematodes and ectoparasites, but is without effect on cestodes and trematodes.

Resistance to Ectoparasiticides

Resistance has been widely reported for many popular ectoparasiticides such the avermectins, pyrethroids, and OPs. Resistance also tends to occur where there is intensive use of antiparasitic drugs, even on “well-managed” farms. There is some concern that as the newer insecticides such as the neonicotinoids become more frequently and inappropriately used, resistance can potentially emerge. However, there is little or no evidence of fleas developing resistance to the increasing and popular use of imidacloprid (Schroeder et al., 2003). Mechanisms of resistance may be related to decreased penetration, increased detoxification enzyme activity, and decreased sensitivity of the target site. These mechanisms have been more recently elucidated from a molecular basis using annotated insect genomes and recognizing that insect resistance is mediated by complex multigene enzyme systems. Pyrethroid resistance amongst insects has been associated with mutations in the sodium channel genes reducing the ability of the insecticide to bind to the sodium channel. Although resistance to imidacloprid has not been demonstrated in cat fleas, mutations in nicotinic acetylcholine receptors have been associated with some agronomic insects being resistant to this new class of insecticides (Liu et al., 2005).

Cross resistance for a specific target site is indeed very common within individual insecticide classes. However, cross-resistance across different target sites is a more severe consequence and limits insect management. Detoxification mechanisms are often the source of cross-resistance between insecticides that differ in their mechanisms of action. These detoxification enzymes include the carboxylesterases, cytochrome P450s, and glutathione-*S*-transferases, which are often implicated in pyrethroid and OP resistance. In a more recent observation, point mutations in the *Rdl* gene in a field population of cat fleas conferred cyclodiene resistance and cross-resistance to fipronil, which is one of the few new chemicals on the commercial market (Daborn et al., 2004).

Table 43.1 Chemical structures and physicochemical properties of common ectoparasiticides

Name	Chemical name (empirical formula) [molecular weight] Log P	Chemical structure

Strategies that can prevent or delay resistance include: (i) appropriate selection of insecticides, (ii) insecticide rotations and mixtures, (iii) limited interactions with agricultural pesticides, and (iv) resistance monitoring. The latter is a major issue when it comes to treating fleas as there are no universally susceptible strains of cat flea known (Rust, 2005). However, the use of various genetic tools such as TaqMan-allele-specific amplification provide a promising method for assaying large populations of insects for insecticide resistance to the newer chemicals on the commercial market. With this in mind, the reader is encouraged to consult reviews (ffrench-Constant et al., 2004) on how the new genetic tools are addressing insecticide resistance.

Fipronil

Fipronil was first approved in 1996 for use in dogs and cats to treat for fleas and ticks. This chemical has been marketed as Frontline® Top Spot and Frontline® Plus for dogs, puppies, cats, and kittens, and Frontline® Spray Treatments for cats and dogs. The Plus product indicates that fipronil was formulated with methoprene, which is an insect growth regulator (IGR) (methoprene is discussed in more detail in Section Insect Growth Regulators). The TopSpot product contains 9.7% fipronil and the Spray contains 0.29%. A more recent fipronil formulation is Frontline® Tritak for dogs (9.8% fipronil, 8.8% methoprene, and 5.2% cyphenothrin) and Frontline® Tritak for

Table 43.2 Mechanisms of action of ectoparasiticides against the parasite and signs of mammalian toxicity

Drug	Mechanism of action	Signs of toxicity
Fipronil	Noncompetitively block passage of Cl ions through GABA- and glutamate-gated channels	Hyperactivity and convulsions related to GABA antagonism
Imidacloprid	Competitive inhibition at postsynaptic nicotinic acetylcholine receptors (nAChR) leads to influx of Na ions	Nicotinic effects (tremors)
Avermectins	Target glutamate-gated chloride channels	CNS depression and ataxia Target GABA- and glycine-gated chloride ion channels
Pyrethrins and pyrethroids	Target voltage-gated Na ion channels in axonal membrane	Type 1 syndrome (tremors, hyperexcitability) Type 2 syndrome (salivation, weakness)
Organophosphates and carbamates	Inhibition of acetylcholinesterase (AChE)	Muscarinic and nicotinic effects (miosis, tremors, depression)
Amitraz	Inhibits monamine oxidase	Activates α_2-adrenergic receptors (CNS depression)
Insect growth regulators	Falsely signals insect to remain immature stage Inhibition of chitin synthesis	No known toxic signs
Synergists	Inhibit cytochrome P450	Can potentiate drugs and pesticides

cats (9.8% fipronil, 11% methoprene, and 15% etofenprox). Cyphenothrin and etofenprox are pyrethroid or pyrethroid like and are discussed in Section Pyrethrins and Synthetic Pyrethroids.

Chemistry

This insecticide is classified as a phenylpyrazole with the molecular formula: $C_{12}H_4Cl_2F_6N_4OS$. Fipronil has a molecular weight of 437.15 and log P (n-octanol/water) of 4.0, and solubility of 2 mg/l in water and >10,000 mg/l in corn oil (Budavari, 1996). This high affinity for oils in the skin partly explains why dermal absorption is limited.

Pharmacokinetics

Topical application of the fipronil formulation between the shoulder blades is believed to result in surface translocation of the chemical over the entire body with significant deposition in sebum, sebaceous glands, and hair follicles. In effect, the sebaceous glands act as a reservoir, which continuously secretes firponil out of the hair follicle forming a layer on and in the stratum corneum and fur of the animal. Recognizing that 95% effective flea control requires 0.7 μg fipronil/g fur, as much as 4.5 μg/g and 1.6 μg/g have been detected in cats at 42 days and dogs at 56 days, respectively. Dermal absorption of ^{14}C-fipronil was less than 1% of the applied dose for all doses tested (0.88–48 mg/rat) and up to 24 hours exposure (Cheng, 1995).

Mechanism of Action

Fipronil acts on the central nervous system where it appears to be primarily effective in noncompetitively blocking the passage of chloride ions through GABA-gated and glutamate-gated chloride channels in ectoparasites. The latter mechanism exits in ectoparasites, but not mammals, suggesting that there are multiple insect target sites for this drug. A study has demonstrated that fipronil and its metabolite, fipronil sulfone, are potent inhibitors at these sites (Zhao et al., 2005). In mammals, fipronil binding to the GABA receptor is also less effective, which also accounts for its wide margin of safety. Fipronil sulfone has a higher potency than fipronil in mammalian GABA receptors and simultaneous exposure to other drugs that potentiate formation of the metabolite could potentially be toxic to mammals in these scenarios. However, data from the literature is conflicting as to whether metabolic conversion to the sulfone derivative represents detoxification. For example, pretreatment of mice with a cytochrome P450 oxidase inhibitor, piperonyl butoxide, increased the toxicity of fipronil by as much as sevenfold (Hainzl and Casida, 1996). Prior to its veterinary approval, fipronil was and is still approved for use in plant agriculture; however, photochemical conversion can result in a desulfinylated photoproduct that is 10-fold more potent than firponil at the mammalian chloride channel. Whether this will be concern for livestock that forage on exposed pastures is still to be determined.

Efficacy

Fipronil as a topical spray is effective against adult fleas, all stages of brown dog ticks, American dog tick, lone star ticks, and deer ticks. This product is approved for dogs, cats, and puppies or kittens (>8 weeks), and can provide protection for up to 30 days. The manufacturers claim that although the Topical Spot On product can be effective against fleas for as long as 3 months they still recommend that it be applied every month. Fipronil (9.8%) formulated with 8.8% *S*-methoprene (dogs) or 11% *S*-methoprene (cats) (Frontline® Plus), an insect growth regulator, is not only an effective adulticide, it also kills flea eggs and flea larvae. While excellent ectoparasiticidal efficacy against fleas, ticks, and chewing lice has been proven, there has been some concern about its repellent effects against ticks and also ticks already on the animal (Denny, 2001; Young et al., 2003). Compared to some pyrethroids and some OPs, fipronil is also not effective in preventing fleas from biting and feeding within the first hour of infestation and prior to being killed (Franc and Cadiergues, 1998). Firpoil is effective for the treatment and control of biting lice (*Trichodectes canis*) in canine infestations (Pollmeier et al., 2002, 2004). The label also claims that this drug can aid in the control of sarcoptic mange infestations. Note that Frontline® Tritak™ for dogs is different from that for cats in that different pyrethroids are used in the formulations and applicators should be aware of this difference (see discussion on pyrethroid esters and pyrethroid ethers later in Section Pyrethrins and Synthetic Pyrethroids).

Safety/Toxicity

Fipronil appears to have a wide margin of safety (rat dermal LD_{50} = 2000 mg/kg), and thus is regarded as a lower order of toxicity when used in veterinary applications. No adverse effects have been observed at five times the maximum dose rate in dogs and cats. However, slight skin or eye irritation have been observed after skin and eye exposure, respectively (Rhone Merieux, 1997). The oral and dermal LD_{50} in rats is 100 mg/kg and >2000 mg/kg, respectively (Budavari, 1996). Like the avermectins and organochlorines, fipronil's mechanism of action involves GABA receptor antagonism. At toxic doses, it can cause hyperactivity, hyperexcitability, and convulsions, which are correlated with increased spontaneous nerve activity and generation of prolonged high-frequency discharges with nerve stimulation. These symptoms are associated with blockage of the neuronal inhibition or membrane hyperpolarization because these antagonist are also blocking chloride uptake. This in effect results in stabilization of the GABA-bound form of the chloride channel (Bloomquist, 2003).

There appears to be no reported interactions between firponil and approved companion animal drugs and ectoparasiticides. Animals exposed to large doses of firponil via accidental oral absorption are expected to display seizures, and neurological and hepatic function should be monitored (Hovda and Hooser, 2002). Extralabel use in young or small rabbits can cause seizures and death. Multigenerational rat studies have concluded that this drug is not mutagenic or teratogenic.

Neonicotinoids

Imidacloprid

Imidacloprid has been approved for use in crop agriculture as a systemic insecticide as well as for treating adult fleas on dogs and cats. Amongst the many imidacloprid products, it is available as Advantage® (9.1% imidacloprid) for adult fleas and Advantage® II (9.1% imidacloprid and 0.46% pyriproxyfen) to target adult and early life stages of fleas. It is also formulated at 8.8% w/v with permethrin (44% w/v) in K9 Advantix® II to treat for fleas as well as ticks. The latter is approved for use in cats and not dogs because cats do not tolerate permethrin as well as dogs. Advantage Multi® (10% imidacloprid and 2.5% moxidectin for dogs/1.0% for cats) is a once a month application approved for dogs and cats to treat for adult fleas, intestinal worms, and prevent heartworm disease as well as treat sarcoptic mange in dogs and control ear mites in cats.

Chemistry

Imidacloprid belongs to a relatively new class of synthetic insecticides known as the neonicotinoids. Imidacloprid (chloronicotinyls nitroguanidine) more specifically belongs to the chloronicotinyls that were first synthesized in 1985. This chemical was found to have 62 to more then 3000-fold greater insecticidal activity than the nicotinoids (e.g., nicotine), and was introduced into the commercial market in 1991. These chemicals are photostable, which ensures prolong residual efficacy, and they are moderately soluble in water (0.51 g/l). The log octanol water partition coefficient of imidacloprid is 0.57 and it has a molecular weight of 255.7. Unlike the nicotinoids, the neonicotinoids are not ionized at physiological pH. Neonicotnoids therefore more readily penetrate the CNS of insects than nicotinoids because the former has a greater hydrophobicity. This physicochemical difference in physiological conditions partly explains why the neonicotinoids have greater insecticidal activity than the nicotine-based insecticides.

Pharmacokinetics

Topical application of imidacloprid to the skin does not result in significant dermal absorption into the blood stream, but rather surface translocation aided by body movement results in whole-body coverage. Its efficacy is dependent on contact with the flea at the surface of the animal's skin. Results from metabolism and toxicokinetics studies in other vertebrates suggest that if this chemical becomes systemic, then it is widely distributed to organs, but not to fatty tissues or the central nervous system (Sheets, 2001).

Mechanism of Action

At the nicotinic cholinergic synapse, acetylcholine (ACh) is normally released from the presynaptic membrane and by binding to the postsynaptic membrane this results in a conformational change in the receptor molecule that leads to activation and opening of the ion channel and subsequent influx of extracellular Na^+ and efflux of K^+. This results in change in membrane potential, and propagation of nerve impulse. Imidacloprid essentially mimics the effects of ACh by competitive inhibition at the postsynaptic nicotinic acetylcholine receptors (nAChR) and little or no effect on muscarinic acetylcholine receptors (Buckingham et al., 1997; Tomizawa and Casida, 2003). The former are widely and predominantly distributed in the neuropil regions of the CNS in insects, and imidacloprid is highly specific for nicotinic receptor subtypes unique to insects. However, instead of a depolarization of the postsynaptic neuron and transmission of the nerve impulse as normally seen with acetylcholine, imidacloprid causes a biphasic response. This consists of increased frequency of spontaneous discharge followed by a block in nerve pulse propagation along the neurons and then insect death (Schroeder and Flattum, 1984). Muscarinic receptors and other types of nicotinic receptors in mammals do not bind imidacloprid effectively, which accounts for its selectivity for insects (Kagabu, 1997). There is, therefore, no surprise that adverse effects are not observed when dogs were topically exposed to greater than the recommended dosage. Readers should be aware that although the neonicotinoids are selective, the nicotinoids are less selective and therefore more toxic to vertebrates than the neonicotinoids.

Efficacy

Compared to fipronil and selamectin, imidacloprid appears to be more readily taken up by the flea via body contact (Mehlhorn et al., 2001). This study demonstrated that imidacloprid killed larvae and adult fleas within 1 hour of exposure, while similar efficacy was achieved with the other two chemicals within 24 hours. It should be noted that none of these three chemicals had any repellent activity against fleas. Imidacloprid can kill 98–100% of adult fleas for at least 4 weeks on dogs and cats. This chemical has limited activity against ticks. Imidacloprid also stops fleas from biting within 3–5 minutes after application although the fleas do not die within this short time frame. Among the product claims for Advantage II® is the ability to kill fleas within 12 hours of application. This clearly is useful for preventing flea allergy dermatitis. Earlier studies demonstrated that shampooing or water exposure does not significantly reduce the efficacy of imidacloprid for up to 28 days (Cunningham et al., 1997).

In fall 2002, Bayer Corp. received registration from EPA for a topical ectoparasite K9 Advantix™, which is a topical insecticide formulated with imidacloprid and permethrin to repel and kill mosquitoes, ticks, and fleas on adult dogs and puppies 7 weeks of age and older for up to 4 weeks. The product's efficacy is not affected by swimming or bathing activities. Imidacloprid acts on the postsynaptic nicotinic receptor by "locking" it in the open position thus hyperstimulating the neuron, and permethrin keeps open the Na^+ ion exchange channels causing constant nerve impulses. Recall, that these would normally close after transmitting an impulse. There is, therefore, a synergistic interaction on the nervous system that is associated with an overwhelmed parasite nervous system, followed by rapid paralysis and death of the parasite. Due to their unique physiology and inability to metabolize certain compounds such as the pyrethroid (reduced glucuronidation activity in cats), this product must *not be given to cats.*

Safety/Toxicity

Clinical signs of toxicity are usually associated with nicotinic effects (e.g., tremors) and hepatic effects when dogs were exposed to a high dose of 41 mg/kg in the diet (Hovda and Hooser, 2002). However, except for one single reported case in cats (Godfrey, 1999),there are no published reports of imidocloprid causing systemic toxicity in domestic animal species following dermal exposure. The chemical does not appear to cause dermal irritation nor does it appear to cause dermal sensitization, although there are very rare anecdotal reports of adverse skin reactions. Imidacloprid does not appear to be a teratogen, reproductive toxicant, mutagen, or carcinogen (Sheets, 2001). The available products should not be given to puppies or kittens younger than 4 months.

Nitenpyram

Nitenpyram (Capstar™) is in the same class as imidacloprid (i.e., chloronicotinyl), and therefore has the same mechanism of action. This is, however, not a topical application, but an *oral adulticide* that is used against fleas in dogs and cats.

Chemistry

Nitenpyram, like imidacloprid, belongs to the new class of synthetic insecticides known as the neonicotinoids. Nitenpyram has a molecular weight of 270.72, a log octanol water partition coefficient of −0.64, and water solubility of 840 g/l.

Pharmacokinetics

Nitenpyram is readily absorbed (bioavailability = 100%) in the gastrointestinal tract with the time to maximum blood concentration being 1.21 hours in dogs and 0.63 hours in cats. The C_{max} is about 4.3 to 4.8 ppm in both dogs and cats, which is significantly greater than the blood concentration of 0.5–1.0 ppm nitenpyram required to kill 100% of the fleas. The half-life in dogs and cats is 2.8 hours and 7.7 hours, respectively, and it is primarily excreted in the urine.

Efficacy

The recommended minimum oral daily dosage is 1 mg/kg in tablet form with or without food and as often as once per day when fleas are seen on the animal. One dosage form (11 mg) is for cats and dogs up to 11 kg, and the other dosage form (57 mg) is for dogs between 11 and 57 kg. This chemical is also very effective against fleas that have become resistant to fipronil (Schenker et al., 2001). Based on the above pharmacokinetics, it is no surprise that fleas begin falling off of the coat of dogs and cats within 0.5 hours of administration of this drug (Rust et al., 2003; Rust, 2005). Efficacy reaches 98.6% in dogs and 98.4% in cats within 6 hours.

Safety/Toxicity

The acute oral LD_{50} in male rats is 1680 mg/kg, which suggest that this chemical is very safe. Ten times the recommended dose did not appear to cause adverse health effects in 7 to 8-month-old cats and 7-month-old dogs (Witte and Luempert, 2001). In the same study, administration of one, three, or five times the recommended daily dose for 6 months resulted in no adverse health effects in dogs and cats that were initially 8 weeks old. The drug is well tolerated for daily doses in puppies and kittens that are >4 weeks. No adverse reactions were observed when used with most other drugs or ectoparasiticides such as topical, carbaryl, fipronil, pyrethin, or even imidacloprid, which has a similar mechanism of action (Witte and Luempert, 2001). A transient itching period observed in dogs and cats within 1-2 hours after treatment with this product appears not to be associated with the chemical irritation, but attributed to fleas displaying increased trembling activity before dying and falling off the animal (Mahoney et al., 2001).

Spinosad

This neonicotinoid, which is a mixture of spinosyn A and spinosyn B (17 : 3 ratio), was approved in 2007 for once a month use in dogs, and in 2012 for cats (e.g., COMFORTIS® Chewable Tablets). Spinosad at 30 mg/kg dose is also formulated with milbemycin oxime (0.5 mg/kg) as TRIFEXIS® was introduced in 2011 for use in dogs only to prevent heartworm, treatment and control of fleas, and adult hookworm, roundworm, and whip worm. It has been used in sprays, dips, and pour-ons for sheep to control lice and blowfly strike in some countries. It is a contact and systemic insecticide and acaricide. Spinosad is quickly absorbed to blood after oral absorption. Oral bioavailability is greater than 70%, especially when administered with food, resulting in maximum plasma levels at 2 to 4 hours after administration. The mechanism of action is associated with activation of nicotinic acetylcholine receptors of the nerve cell membranes of insects that are different subunit targets from those of other known neonicotinoids. This limits the possibility for cross-resistance with similar related insecticides.

Safety/Toxicity

Adverse reactions are rare in dogs and cats and vomiting may be observed on the day of, or the day after, administration. The oral LD_{50}, in rats is 3600 mg/kg, suggesting that spinosad is very safe in spite of anecdotal reports of adverse effects of Triflexis® in 2014 that appeared to be unrelated to the active ingredients of this products but point to other unrelated factors. It should, however, be noted that there is the possibility for drug–drug interactions between spinosad and ivermectin as spinosad could inhibit the drug transporter P-glycoprotein (P-GP) which is also a substrate for ivermectin (Schricky, 2014). This finding may conflict with results from another study where 20 adult Collies homozygous or heterozygous for the *MDR1* gene mutation were dosed with combinations of spinosad and milbemycin at five time and 10 times the label dose, respectively, and there were no observed adverse effects related to these chemicals such as depression, ataxia, mydriasis, and hypersalivation (Sherman et al., 2010). In spite of these observations, the manufacturer has reported on its label that its postapproval experience has seen these adverse effects associated with concomitant use of extralabel ivermectin and not with the label use of ivermectin.

Dinotefuran

This neonicotinoid is approved for dogs and cats and has the same mechanism of action against fleas as described for the previously described neonicotinoids. One product, Vectra for Dogs™, which contains 22% dinotefuran and 3% pyriproxyfen, claims to provide effective monthly control of adult fleas, flea eggs, flea larvae, and flea pupae. Pyriproxyfen is a juvenile-hormone analog, which controls the immature stages of the flea.

Isoxazolines

The isoxazoline class of antiparasiticides have both insecticidal and acaricidal activities. Afoxolaner (NexGard®) is an isoxazoline that was first introduced in 2000 and in 2013 as a veterinary product with a labeled dose of 2.5 mg/kg to treat for fleas and ticks in dogs as a chewing tablet. The more recent isoxazoline, fluralaner (Bravecto®), was approved in 2014 by US FDA at a label dose of 25 mg/kg as a chewable tablet to control flea and ticks. Both of these chemicals are very lipophilic. Afoxolaner has a molecular weight of 625.87 and log octanol water partition coefficient of 6.7, while fluralaner has a molecular weight of 556.29 and a log octanol water partition coefficient of 5.35.

Pharmacokinetics

Following oral administration of 2.5 mg/kg afoxalaner as chewable tablet, the absolute bioavailability was 74% with a mean maximum plasma concentration (C_{max}) of 1.65 ± 0.33 μg/ml at 2–6 hours (T_{max}) (Letendre et al., 2014). In another study, liquid formulations of afoxalaner dosed at 2.5 mg/kg resulted in highest C_{max} value of 0.82 μg/ml and lowest C_{min} value of 0.09 μg/ml at 30 days postdose (Shoop et al., 2014). In vitro and in vivo assays determined that 0.16 μg/ml provided 100% control at 24 hours and Letendre et al. (2014) reported that the EC_{90} for fleas (*Ctenocephalides felis*) and ticks (*Rhipicephalus sanguineus* and *Dermacentor variabilis*) to be 0.023 μg/ml and >0.1 μg/ml, respectively. Afoxalaner appears to be widely distributed (volume of distribution = 2.68 ± 0.55 l/kg) in the body of the dog, although plasma protein binding is high (99.9%). This drug has a low systemic clearance (4.95 ± 1.20 ml/h/kg). Ultimately, the terminal plasma half-life is long in dogs (approximately 2 weeks), although there can be breed differences; the half-life of afoxalaner in Collies can be as long as 47 days. The chemical is metabolized in the liver (low extraction ratio) with metabolites and parent being eliminated via urinary and biliary excretion, with the latter being more important than the former and limited evidence of enterohepatic recycling.

The pharmacokinetics for fluralaner in dogs was very similar to that for afoxalaner. Oral and intravenous studies reported a low systemic clearance (5.83 ml/kg/h), large volume of distribution (3.2 l/kg) in spite of it high plasma protein binding, and long apparent half-lives from 12–15 days (Kilp et al., 2014). Oral bioavailability ranged from 20 to 34% and the drug plasma concentration was >0.01 μg/ml for the high dose of 50/kg at

112 days posttreatment No dogs showed any signs of toxicity following oral doses of 12.5, 25, or 50 mg/kg.

Mechanism of Action

Isoxazolines inhibit GABA-gated chloride ion channel inhibitors with nanomolar potency (Shoop et al., 2014). Glutamate-gated chloride ion channel receptors have also been implicated (Woods et al., 2011). This results in an irreversible hyperexcitation in targeted insects and ticks. Although GABA-gated chloride ion channels are the target for many other ectoparasiticides on the market (e.g., avermectins, fipronil, and cyclodiens), the isoxazolines bind to a different site and, furthermore, the avermectins activate rather than block these ion channels. It should be noted that the isoxazolines are more selective for the GABA receptor in insects and tick than those receptors in mammals.

Efficacy

The recommended minimum oral daily dosage for afoxolaner is 2.5 mg/kg in tablet form once a month. This chemical, as expected from the pharmacokinetics, is very effective against fleas (*Ctenocephalides felis* and *C. canis*) and ticks (*Dermacentor reticulatus, Ixodes ricinus, Rhipicephalus sanguineus*). Fleas will be exposed to the chemical following attachment and feeding and the onset of effect can occur within 8 hours of attachment; for ticks, the onset of death is within 48 hours of attachment. Fluralaner (Bravecto) should be administered orally as a single dose every 12 weeks. It quickly kills fleas and the tick species such as *Ixodes, Dermacentor*, and *Rhipicephalus* within 12 hours and also kills *Amblyomma americanum* (lone star tick) if the drug is administered every 8 weeks instead of 12 weeks.

Safety/Toxicity

As indicated above, these drugs are very selective for fleas and tick nervous system compared to mammalian nervous system. No adverse effects have been observed in dogs receiving doses five times the label dose. Adverse reaction in dogs have been rare thus far, although vomiting, diarrhea, lethargy, and anorexia have been observed. These products have not been evaluated in pregnant, breeding, or lactating dogs, therefore caution should be exercised when administering these dogs.

Macrocyclic Lactones

These macrolides consist of two major groups, avermectins and milbemycins, which are effective against many ectoparasites, as summarized in Table 43.3. The avermectins include ivermectin, eprinomectin, doramectin, and selamectin and the milbemycins include moxidectin and milbemycin oxime. These compounds are also discussed in Chapter 41.

Table 43.3 US FDA approved ectoparasiticides[a]

Drug class	Approved species	Ectoparasite approved indications
Avermectins/milbemycins		
Ivermectin	Cats	Ear mites
	Beef cattle	Lice, mites, ticks, grubs
	Pigs	Lice, mites
Doramectin	Beef cattle	Lice, mites, ticks, grubs
	Pigs	Lice, mites
Pour-on eprinomectin	Dairy and beef cattle	Lice, mites, flies, grubs
Injectable eprinomectin	Beef only	Lice, mites, flies, grubs
Selamectin	Dogs	Fleas, mites, ticks
	Cats	Fleas, mites
Moxidectin	Dairy and beef cattle	Lice, mites, flies, grubs
Milbemycin	Cats	Ear mites
Organophosphates		
Fenthion	Beef cattle	Grubs, lice, flies
Famphur	Beef cattle	Grubs, lice, flies, ticks
Amitraz	Dogs	Mites
	Dairy and beef cattle	Lice, mites, ticks
	Swine	Louse, mites
Nitenpyram	Dogs and cats	Fleas
Lufenuron	Dogs and cats	Fleas

[a] Approved as of March 2015.

Chemistry

Both avermectin and milbemycin groups are 16-membered macrocyclic lactones. The avermectins are products of *Streptomyces avermitilis* that have the 16-membered macrocycle replaced by a spiroketal unit at C-17 to C-28, a hexahydrobenzofuran at C-2 to C-8a, and a bisoleadrosyloxy disaccharide at C-13. The milbemycins are also products of *Streptomyces* and are structurally similar to the avermectins, but *lack the sugars at C-13.* The latter group is believed to enhance antiectoparasite activity. The nemadectins are classified as milbemycins, but differ from the milbemycins proper because they have a distributed double bond at C-26. An important nemadectin is moxidectin (e.g., Cydectin)**.** Eprinomectin (4″-epi-acetylamino-4″-deoxy-avermectin B1) is a true second-generation macrocyclic lactone synthesized from avermectin. Doramectin differs from ivermectin in that a six-carbon ring replaces a three- or four-carbon chain at the C-25 position of the basic ivermectin. Compared to ivermectin, these molecular differences result in a more lipophilic and persistent doramectin molecule.

Pharmacokinetics

The oral, IV, and SQ pharmacokinetics have been described in Chapter 41 of this book. The focus here will be to compare the dermatopharmacokinetics of topically applied avermectins. It should be first noted that eprinomectin and moxidectin pour-ons are formulated in >80% oil content. This encourages more drug depot formation on skin surface and stratum corneum, and thus *reduced bioavailability* compared to pour-on products with ivermectin and doramectin. The latter are formulated with isopropyl alcohol, which is more likely than oil to promote epidermal flux. Because of the high oil content of the eprinomectin and moxidectin formulations, there is evidence that it is water-fast and thus tolerant to rain and other forms of weather precipitation (Gogolewski et al., 1997).

The dermal bioavailability of doramectin is about 40% greater than ivermectin in cattle (Gayrard et al., 1999). The dermal bioavailability for doramectin pour-on is approximately 16% when compared to the subcutaneous route of administration. Following topical application of selamectin, this drug is slowly absorbed (flip-flop kinetics) into the blood stream and redistributed to form reservoirs in sebaceous glands as well as the hair follicle and basal cells of the epidermis (Sarasola et al., 2002). Dermal bioavailability appears to be significantly greater in cats (74%) than in dogs (4.4%), although this may be attributed to greater self-grooming in cats than in dogs. However, selamectin flux is three times greater in cat skin (0.1 $\mu g/cm^2/h$) than in dog skin (0.03 $\mu g/cm^2/h$). The half-life of this drug is greater in cats (69 hours) than in dogs (14 hours), and, in general, selamectin half-life is greater in cats and dogs following dermal > oral > IV administration. This demonstrates its persistence in the stratum corneum and upper epidermis. As with many of the avermectins, the dermal absorption process is the rate-limiting step, and the increased persistence in the body after dermal application should reduce reinfection rates by ectoparasites. There is also conflicting evidence of differences in selamectin disposition between male and female dogs (Sarasola et al., 2002; Dupuy et al., 2004).

Mechanism of action

In invertebrates, the avermectins primarily target the glutamate-gated chloride ion channels, but which are close in proximity to GABA-gated sites. It is possible that these endectocides may also potentiate GABA-gated sites. Chloride influx lowers cell membrane resistance and causes hyperpolarization of the resting potential of postsynaptic cells. Transmission to muscles is therefore prevented. The ectoparasite therefore displays ataxia, paralysis, and death. In contrast to GABA antagonists (e.g., lindane and fipronil) that lead to convulsions, the avermectins cause a different neurological syndrome that is characterized at first by a coarse tremor followed by ataxia and coma-like sedation. It should be noted that the avermectins can block GABA at low concentrations, but at high concentrations cause irreversible channel activation or enhancement of GABA effect, which is associated with at the classical signs of ataxia and sedation. These endectocides have a wide margin of safety because they are very selective for the glutamate-gated channels in nematodes and arthropods, but which are lacking in mammals. In mammals, the avermectins primarily target the GABA-gated, and possibly the glycine-gated, chloride channels (Bloomquist, 2003). Furthermore, in mammals, GABA-mediated neurotransmission occurs in the CNS, where the blood–brain barrier prevents uptake of the endectocides. These endectocides are also thought to interfere with parasite reproduction. It should be noted that unlike the macrolide antibiotics, these endectocides lack antibacterial and antifungal activity.

Efficacy

Ivermectin

Injectable formulations are used to control lice (*Haematopinus suis*) and mange mites (*Sarcoptes scabiei var. suis*) in swine and horn flies (*Haematobia irritans*), grubs (*Hypoderma bovis*), biting and sucking lice (*Lignathus vituli, Haemaotopinus eurystemus*), and mites (*Sarcoptes scabei var. bovis*) in cattle. Pour-on and oral formulations are also available for cattle. There is *no* immediate death to ticks in cattle, but reduced reproductive potential. As these drugs are eliminated in the feces, they are effective against dung-breeding flies. Not all commercial formulations of ivermectin are approved for the treatment of the most common type of cattle mange caused by chorioptic mite. In dogs**,** SC doses can be effective against otodectic, sarcoptic, and notoedric mange and control of demodectic mange. In cats a relatively new topical product (Acarexx®) is approved for treating adult ear mites (*Otodectis cynotis*) in cats and kittens 4 weeks of age and older. There is evidence that the ears do not necessarily need to be cleaned before treatment.

Eprinomectin

This drug is available as a pour-on formulation (Eprinex®) at 0.5 mg/kg for both dairy and beef cattle and it is also available as an extended-release subcutaneous injection (LongRange®) at 1.0 mg/kg for beef cattle only. The correlation between pharmacokinetics of macrocyclic lactones and the persistence of the antiparasitic activity has been a difficult exercise, but several investigators have estimated that minimal drug plasma concentrations between 0.5 and 1 ng/ml should be adequate for nematocidal activity, while others have suggested minimum levels of 1 to 2 ng/ml (Shoop et al., 1996; Lifschitz et al., 1999, 2008). The eprinomectin pour-on formulation resulted in plasma concentrations above 0.5 ng/ml for at least 21 days (Alvinerie et al., 1999) while the extended-release injectable formulation maintained plasma concentrations above this level for at least 150 days.

The pour-on formulation provides approximately 20–50 days of parasite control, depending on the species, while the injectable formulation provides up to 100–150 days of parasite control. The pour-on formulation is an oil-based formulation that makes the drug "waterproof" to some extent. This broad-spectrum antiparasiticide is effective against lice, hornflies, and mites. Because of its unique molecular structure and route of application, the pour-on eprinomectin at the label dose does not readily partition into milk. The milk/plasma ratio can range from 0.07 to 0.17 (Shoop et al., 1996; Alvinerie et al., 1999), and therefore is the one of few pour-on endectocides that requires *no* milk withholding time. The meat withdrawal time is also zero for the pour-on formulation. However, the injectable eprinomectin formulation, LongRange®, is only approved for beef cattle and not dairy cattle and the meat withdrawal time is 48 days.

Doramectin

Doramectin is available as an injectable for beef cattle (0.2 mg/kg SC and IM) and swine (0.3 mg/kg IM) and pour-on (0.5 mg/kg) for beef cattle only. It is believed to be more efficacious than other endectocides against biting and sucking lice. This drug is not approved for dairy cattle because of the concern for significant residues in milk. In cattle, the spectrum of activity is similar to that of ivermectin. Doramectin has activity against important sucking lice, grubs, ticks, mites, and screwworms in cattle. The latter is unique among the macrolide endectocides. Application of the pour-on can prevent reinfestation of lice for as long as 16 weeks. In swine, doramectin is approved for use against sucking lice and mange mites.

Moxidectin

Moxidectin products (Cydectin®, Equest®) are a new generation of milbemycins that have a broad spectrum of activity against nematode and arthropod parasites in cattle. Unlike the previously discussed endectocides, this is a single compound, and not a mixture of two compounds. The approved dose of Cydectin® pour-on is 0.5 mg/kg in cattle, and the drug has a spectrum of activity similar to ivermectin. Cydectin® *is the only pour-on endectocide labeled for control of common scab mite* (*Psoroptes ovis*), a reportable disease requiring quarantine.

Selamectin

Selamectin (Revolution®) is a topical monthly application approved for treating dogs and cats for ear mites, adult fleas, and prevents flea eggs from hatching. In dogs, it is used in the treatment and control of sarcoptic mange (*Sarcoptes scabiei*) and control of the tick (*Dermacentor variabilis*). Selamectin is the only spot-on product approved for control of canine sarcoptic mange. There are anecdotal reports of delayed responses to this drug and a few treatment failures (Curtis, 2004). However, in lieu of these situations, some veterinary dermatologist recommend that this drug be reapplied every 2–3 weeks with owners consent as this is extralabel use of the drug.

Milbemycin oxime

Milbemycin oxime is well known as a heart worm preventative, but it also has significant ectoparasiticidal effects. The only approved use of this chemical as an ectoparasiticide, Milbemite® Otic Solution, at 0.1% is used as a treatment for ear mite (*Otodectes cynotis*) infestations in cats and kittens 4 weeks of age and older. *Milbemycin oxime* may also be effective in cases of amitraz-resistant demodicosis, but this is not an approved use thus far.

Safety/Toxicity

Ivermectin has a 10-fold safety margin in ruminants, horses, swine, and dogs, except Collies. Due to a mutation within the gene that codes for the MDR1 pump protein that normally disallows entry of ivermectin into the central nervous system, Collies should not be treated with ivermectin or any other avermectin. Acute toxic signs include CNS depression, ataxia, and possible death. The principle clinical pathological change is a decrease in serum iron values in dogs.

The meat and milk withdrawal times for this class of drugs vary across avermectins, and Table 43.4 provides clear evidence of this and why label instructions should be carefully followed. Extralabel use of doramectin or ivermectin in dairy cattle may require a milk withholding period of almost 60 days!

Table 43.4 Withdrawal times of pour-on macrolide endectocides

Generic drug	Example	Approved species	Withdrawal times
Ivermectin	Ivomec®	Beef cattle	48 days for meat
Eprinomectin	Eprinex®	Beef and dairy cattle	0 days for meat and milk
Doramectin	Dectomax®	Beef cattle	45 days for meat
Moxidectin	Cydectin®	Beef and dairy cattle	0 days for meat and milk

Pyrethrins and Synthetic Pyrethroids

The pyrethrins were derived from *Chrysanthemum* plants, while in recent years they have been slowly replaced with synthetic pyrethroids. The latter are more resistant to breakdown, which results in greater residual activity than the pyrethrins. Pyrethrins and pyrethroids are often formulated with insect growth regulators, synergists, and/or repellents to enhance efficacy. The more frequently used in veterinary formulations pyrethroids include permethrin, fenvalerate, cypermethrin, and phenothrin. These may be formulated as pour-ons, spray-ons, barn misters, feed-throughs, and shampoos.

Chemistry

Natural pyrethrins occur as six compounds: pyrethrin I, pyrethrin II, jasmolin I, jasmolin II, cinerin I, and cinerin II (Kaneko and Miyamoto, 2001). The molecular weight of these insecticides range from 316.4 to 374.5 and log Ko/w range from 4.3 to 5.9. The synthetic pyrethroids are structurally similar to the natural pyrethrins, and many of those used in veterinary medicine have a wider range in molecular weights (302.4 to 416.3), log Ko/w (4.6 to 7.4), and LD_{50} (105.8 to 4240 mg/kg). Depending on the literature reviewed, the pyrethroids can be classified in a number of ways. Some authors have grouped them into two broad generations of pyrethroids, with the first generation being characterized as esters of chrysanthemic acid and alcohols having furan ring and terminal side chain moieties. These pyrethroids are sensitive to light and temperature, and are therefore most effective when used indoors. The second-generation pyrethroids, and for that matter the majority of pyrethroids in veterinary use today, have a 3-phenoxybenzyl alcohol in the alcohol moiety and replacement of the photolabile moieties with dichlorovinyl, dibromovinyl substituent, and aromatic rings. These modifications provide excellent insecticidal activity and environmental stability for this class of pyrethroids.

Another classification system groups the pyrethroids into four generations, with the first generation reflecting the same properties as the first generation in the earlier classification scheme. The first generation (e.g., allethrin) are similar to the natural pyrethrin, cinerin I, and therefore lack environmental stability. The second generation (e.g., resmethrin and tetramethrin) are significantly more stable than the first generation and have significantly greater killing capacity than the natural pyrethrins. The third generation include the ever popular pyrethroids, fenvalerate, and permethrin, which are noted for their photostability and potency. Permethrin in particular is the most ubiquitous pyrethroid formulated with veterinary ectoparasiticidal products. The fourth generation are the most potent of the pyrethroids (e.g., cypermethrin and cyfluthrin) and also the most persistent. For this reason they are most often formulated in ear tags.

Pyrethroids are also classified as type 2 pyrethroids (e.g., fenvalerate) because they have an alpha-cyano moiety and type 1 pyrethroids (e.g., permethrin), which lack this moiety and thus are less toxic than type 2 pyrethroids. The reader should be aware that these pyrethroid insecticides can exists as chiral and geometrical isomers with some isomers displaying different pharmacokinetic and pharmacodynamic properties from other isomers of the same pyrethroid. Many of these chemicals are stable in weakly acidic water, but very unstable in alkaline medium.

Pharmacokinetics

Dermal absorption of pyrethrins and pyrethroids is indeed very limited (<1%) across the skin of domestic and laboratory animals and humans (Baynes and Riviere, 2001). This is primarily because these chemicals are very lipophilic (Ko/w range from 4.0 to 7.4) and they have large molecular weights. There is therefore the tendency for these chemicals to reside in the outermost layer of the skin (stratum corneum) with little or no penetration into the systemic circulation. For this reason, the pyrethroids are approved by US EPA and *not* the US FDA. These chemicals are also rapidly detoxified to harmless alcohol and acid metabolites and conjugates in the liver and blood with half-lives ranging from a few minutes to typically a few hours (Ray, 2005). The *trans* isomers are hydrolyzed at a faster rate than the *cis* isomers, and the presence of a α-cyano group in the third and fourth-generation pyrethroids also slows down hydrolysis and oxidation. In spite of this, many of these pyrethroids do not result in significant meat or milk withdrawal times following topical administration to food animals (Riviere and Baynes, 1998). For example, there are several approved pour-on products for food animals that contain as much as 1–5% permethrin or 1% cyfluthrin but have zero meat and milk withholding times.

Mechanism of Action

Many different mechanisms of action have been proposed for this class of insecticides. Potential targets in insects include voltage-gated sodium, chloride, or calcium channels, GABA-gated chloride channels, mitochondrial ATPase, and nicotinic receptors, to mention a few of the many proposed targets for pyrethroids. However, the main target is the gating kinetics of Na^+ channels in nerves, which results in repetitive discharges or membrane depolarization and ultimately death of the ectoparasite. Pyrethroids are extremely selective for insects over mammals as insect sodium channels can be as much as

100 times more sensitive than mammalian brain channels (Warmke et al., 1997). In fact, the selectivity ratio (mammalian toxicity vs. insect toxicity) of most pyrethroids exceeds 1000.

Recall that in normal voltage-gated sodium channels it is the inward sodium current that produces the action potential and then it is rapidly closed at normal resting potentials. However, interaction of the pyrethroid with the sodium channel causes the sodium channel to remain open. This leads to a slowing of both the activation and inactivation process, which causes the now modified channel to be in a stable hyperexcitable state. Pyrethroid structure and stereospecificity plays a significant role in the mechanism of action. For example, type 2 pyrethroids such as fenvalerate keep the sodium channel open for a significantly longer period (i.e., prolongation of sodium channel current) than type 1 pyrethroids such as permethrin, which in part explains the differential toxicity between these two classes of pyrethroids. The 1R and 1S *cis* isomers bind competitively while the 1R and 1S *trans* isomers bind noncompetitively to another site. These insecticides, especially the type 2 pyrethroids, could also suppress GABA and glutamate receptor-channel complexes. Pyrethroids are also classified as either type I compounds (permethrin, resmethrin) because they cause rapid onset of hyperactivity and repetitive action potentials or type II compounds (fenvalerate, cypermethrin) because very low doses cause lethal effects and few behavior changes.

Efficacy

Pyrethrins and pyrethroids are formulated in shampoos, sprays, collars, dips, dusts, and ear tags to repel or treat for most of the known ectoparasites important to domestic animals. The discussion below attempts to review the more common application of pyrethroid formulations used in veterinary medicine. Note that these are only examples, and that applications may vary depending on indication (spot-on vs. spray) and this is related to the concentration of the pyrethroid in the formulation. These products may be formulated with synergist and/or insect growth regulators.

First-Generation Pyrethroids

Allethrin (d-trans allethrin) is most often formulated in shampoos for dogs and cats to kill fleas and/or ticks. An excellent example includes Mycodex® SensiCare™ Flea and Tick Shampoo, which has 0.12% d-trans allethrin. First-generation pyrethroids are rapidly metabolized in the body.

Second-Generation Pyrethroids

Phenothrin (85.7%) is frequently used as a spot-on treatment for tick and fleas in dogs only. These spot-on products are *not* approved for cats as of 2005. There are phenothrin flea collars and a shampoo formulation available for both dogs and cats. Resmethrin (0.5%) is more often approved in foggers in stables and kennels, and it also formulated as topical sprays for horses and there are a few shampoo formulations available for control of fleas and ticks on dogs and cats.

Third-Generation Pyrethroids

Permethrin is probably the most widely used pyrethroid in veterinary medicine. Almost all of the spot-on products are at high concentrations and are therefore approve only for dogs, and not cats, to manage fleas, ticks, and mites. The sprays, shampoos, and dusts are formulated at lower concentrations and thus approved for both species. Permethrin is also widely used in food animals as sprays and pour-on to treat for ectoparasites and require short withdrawal times provided the product is correctly diluted and the products are applied no more than every 2 weeks. For example, the Atroban spray products have a 5-day withdrawal time in swine treated with 0.11% permethrin for mange mites but 0 days in cattle treated with 0.02% pemethrin. Many products can have residual activity up to 28 days for some formulations.

Fenvalerate (8%) is formulated in ear tags for cattle to control flies, lice, and ticks. There are no approvals for companion animals.

Fourth-Generation Pyrethroids

Cyfluthrin is approved for use as an ear tag and as a pour-on for cattle (e.g., Cylence®, 1%) with no withdrawal time. As with other pyrethroids there are some concentrates that are approved for use around livestock premises but not directly on animals. These pyrethroids offer the greatest resistance to sunlight exposure. Cypermethrin is usually formulated as a spray and predominantly used as fly repellent around horses with some formulations marketed as being sweat resistant.

Fifth-Generation Pyrethroids

Beta-cyfluthrin is a more potent isomer of cyfluthrin (rat oral LD_{50} = 960 mg/kg). This pyrethroid has been formulated as sprays and ear tags. The ear tags Cylence Ultra™ (8% beta-cyfluthrin) approved for beef and lactating dairy cattle are effective up to 5 months for the control of horn flies, face flies, Gulf Coast ticks, and spinose ear ticks, especially if both ears are used.

Pyrethroid ether

The above pyrethroids are pyrethroid esters, however, in 1987, a new class of related insecticides, known as pyrethroid ethers, were introduced. A good veterinary example of a pyrethroid ether is Etofenprox, which does not contain a cyano group and centers of asymmetry, and therefore has no stereoisomerism as seen in pyrethroid esters. This has been formulated in many dog and cat formulations as sprays and spot-ons with minimal concerns for cats compared to concerns with other pyrethroids in cats. The oral LD_{50} in rats is >42,889 mg/kg and dermal LD_{50} >2140 mg/kg (Harling et al., 1985; Hashimoto et al., 1982). Frontline TritaK for cats (11% etofenprox) is also formulated with fipronil and methoprene in addition to kill fleas, flea eggs, and flea larvae, and starts killing ticks in as little as 1 hour. Of course this chemical combination effectively breaks the flea lifecycle. Etofenprox is also formulated at higher concentrations (e.g., 40%) in other products such Bio Spot Active Care™ Flea and Tick Spot On® for Cats at 40% etofenprox and 3.6% methoprene.

Safety/Toxicity

The selectivity ratio, which compares toxicity in insects with that in mammals, is higher for pyrethrins and pyrethroids (>1000) than for OPs and carbamates (<100). Dermal exposure to pyrethrins and pyrethroids rarely results in systemic absorption to cause significant signs of toxicity in domestic animals, but grooming of the treated hair coat by cats can result in significant oral ingestion of pyrethroids. Cats more so than dogs present with clinical signs of toxicity, and this is oftentimes after the dog formulation was inadvertently applied topically to adult cats or kittens, or the untreated cat comes into physical contact with a treated dog. Recall that cats are deficient in their ability to clear chemicals by hepatic glucuronidation. This explains why cats are more sensitive than dogs to pyrethroids. The dog-only spot-on flea and tick products can contain as much as 45–65% permethrin, which at this concentration can be very harmful to most cats (Meyer, 1999). Not only is permethrin toxicity in cats a great concern, but more recently phenothrin toxicity in cats has also been a concern. Phenothrin, a type 1 pyrethroid similar to permethrin, was originally approved as a spot-on product with 85.7% phenothrin for cats. These products were canceled in 2005 by the manufacturer because of the adverse effects and numerous deaths in feline patients.

Clinical signs of pyrethroid toxicity may be confused with OP or carbamate toxicity, and they include nerve and muscle disorders and can be grouped in type 1 (T) poisoning and type 2 (CS) poisoning. The onset of signs of toxicity can occur within minutes to hours depending on the route of exposure, and the signs may resolve within 24 to 72 hours following supportive therapy. The type 1 syndrome is similar to DDT poisoning in that it involves progressive body tremors, exaggerated startle response, hyperexcitability, and death. Type 2 syndrome is associated with induced salivation, weakness, and distinctive burrowing syndrome. These signs appear in both dogs and cats and large animals, and the prognosis is guarded to good depending on the exposure level. Readers are encouraged to refer to other text and references on appropriate therapy (Richardson, 2000).

Aquatic animals such as fish and invertebrates are highly susceptible to pyrethroids (Smith and Stratton, 1986), therefore their use on and around livestock facilities should ensure there is minimal environmental impact.

Indoxacarb

Inodoxacarb represents the oxadiazine class of insecticides discovered in the 1990s. These pet products, which are used once a month (e.g., Activyl®), are only approved for treating adult fleas, larvae, and eggs but not ticks, lice, mites, and mosquitoes. The products are approved for use in cats and dogs only. The chemical does not need to be absorbed across the skin to get into the systemic circulation for it to be effective. Efficacy is dependent on contact with the flea in the hair coat of the animal.

Mechanism of Action

Once fleas are exposed to indoxacarb, it is rapidly cleaved to its decarbomethoxylated metabolite, which appears to be a potent blocker of voltage-gated sodium ion channels in fleas. There are many other insecticides, such as pyrethroids and organochlorines, that target insect voltage-dependent sodium ion channels, but this chemical has quite distinct actions from the other well-known sodium channel-active commercial insecticides (Lapied et al., 2001). This suggest that there is limited chances for cross-resistance between pyrethroids and indoxacarb products.

Safety/Toxicity

If there is systemic exposure in the pet to indoxacarb, metabolic activation is minor compared to the insect and there are metabolic pathways (indanone and oxadiazine ring cleavage) in mammals that convert indoxacarb mainly to nontoxic metabolites. Furthermore, there is differential sensitivity of sodium ion channels between insects and mammals. Activyl Tick Plus is only for dogs and not cats as this product has permethrin in the formulation, which could cause adverse effects in cats exposed to this product.

Organophosphates

Organophosphates have insecticidal, ascaricidal, and helminthicidal activity, and are thus classified as broad-spectrum ectoparasiticides, which explains why they were used in veterinary medicine for at least four decades since their discovery during WWII. These chemicals are becoming less popular for use in and around domestic animals as there are safer products such as the ivermectins, pyrethroids, neonicotinoids, and firponil. Another concern is related to their persistence in the environment, which can negatively influence the ecosystem. For these and many other reasons, many of the popular OPs which were approved by US FDA or US EPA for use in companion or food animal species are no longer marketed or available for veterinary use. However, there is still sufficient veterinary use of OPs that are US FDA approved (Table 43.3) and US EPA registered and the reader should be aware of their efficacy and be able to recognize signs of OP toxicity in domestic animals.

Chemistry

Organophosphates are usually classified as phosphates (e.g., dichlorvos), phosphorothioates (e.g., coumaphos), or phosphorodithioates (e.g., malathion, fenthion). The term “thioates” indicates that, for some OPs, the double-bonded oxygen is replaced with a sulfur molecule. They can also be classified based on when these chemicals were first developed for commercial use. The aliphatics derivatives were the first OP products and are characterized by their aliphatic like structures (e.g., dichlorvos, malathion). These were followed by the phenyl derivatives, which contain a phenyl ring with one of the ring hydrogens displaced by Cl, NO_2, CH_3, CN, or S (e.g., fenthion, famphur), and then the heterocyclic derivatives where the ring structures are composed of different or unlike atoms such as N or S (e.g., diazonon, chlorpyriphos). The latter group is the longest acting OP based on their chemical structure. The molecular weights of many of these chemicals used in veterinary medicine range from 257 (trichlorfon) to 384 (ethion). These chemicals can be very lipophilic with octanol–water partition coefficients ranging from 2 to 6.

Mechanism of Action

The thioates compounds (P=S) unlike the phosphate (P=O) compounds must first be metabolized in the liver to oxy compounds before they can irreversibly inhibit acetylcholinesterase (AChE) by phosphorylation. Inhibition of AChE results in accumulation of acetylcholine (ACh) at cholinergic receptors. Recall that ACh is a normal neurotransmitter released at synapses that mediates transmission of nerve impulses to effector organs or skeletal tissues to produce a response. AChE is normally present at these nerve endings to rapidly hydrolyze Ach to control the level and duration of synaptic transmission. With OPs inhibiting AChE the resulting accumulation of ACh leads to paralysis and death to the parasite.

Efficacy

As of 2006, there are only 10 OP generics approved for veterinary use in the USA. Systemic bioavailability following topical application is limited, but these chemicals are distributed across the entire coat of the animal by lateral diffusion following topical application to a localized region. Several of these OPs are formulated as topical sprays and dusts or dip application (coumaphos and phosmet), while many are formulated as ear tags in cattle (pirimiphos and diazinon) and flea collars for dogs and cats (tetrachlorvinphos, dichlorvos, and diazinon). Chlorpyriphos and phosmet dips are the only OPs still approved for use in dogs to treat mange. Although chlorpyrifos was recently labeled for restricted use by US EPA, there are several Happy Jack products that are approved for use as shampoos and dips on dogs. These two products are indicated to kill fleas, ticks, and sarcoptic mange mites on dogs. Prior to the availability of avermectins for veterinary use, fenthion (Spotton®) and famphur (Warbex®), which are still US FDA approved drugs, were used extensively to control cattle grubs (*Hypoderma bovis* and *Hypoderma lineatum*) as well as lice. When treating for cattle grubs, the reader should be reminded that application of these therapeutics should occur soon after the heel-fly activity ceases. If the grub larvae are allowed to migrate to the esophagus or spinal canal, rapid killing of large numbers of these larvae following treatment can cause host–parasite reactions such as bloat, salivation, staggering, or paralysis.

Safety/Toxicity

Inhibition of AChE can result in muscarinic and nicotinic effects. The muscarinic effects at the autonomic effector organs include miosis, lacrimation, vomiting, diarrhea, frequent urination, dypsnea, bradycardia, and hypertension. The nicotinic effects include effects at the neuromuscular junction such as muscle tremors and twitching, paresis, and possibly paralysis. Central nervous system signs may include depression, hyperactivity, and seizers, but these are rare events. OP-induced delayed neurotoxicity (clinical signs delayed for 7–21 days) may be observed in dogs and cats following exposure to some but not all OPs. The following drugs may potentiate the toxicity of OPs: phenothiazine tranquilizers, aminoglycoside antibiotics, and neuromuscular blocking agents such as levamisole and nicotine. Brahman, Charolais, and Simmental cattle are more sensitive than English breeds of cattle, greyhounds and whippets are the more sensitive dog breeds, cats are more sensitive than dogs, and poultry are more sensitive than mammals to OPs. Recall that several of these OPs are very lipophilic and potential residues in tissues and milk are possible. Except for fenthion and famphur, many of the currently marketed

OPs approved for use in food animals as of 2006 have a very short or zero withdrawal times as they are less likely to cause residues in meat or milk when used according to label. These are all US EPA registered OPs, and they include coumaphos (Co-Ral®), which has a zero withdrawal time for meat and milk, and phosmet (Del-Phos® Emulsifiable Liquid Insecticide), which has a 3-day and 1-day meat withdrawal time for cattle and swine, respectively. Fenthion and famphur have very long meat withdrawal times which are 46 and 35 days, respectively, and are not approved for us in lactating dairy cattle.

Carbamates

Carbamates are cyclic or aliphatic derivatives of carbamic acid. These insecticides are generally safer than OPs, but they should be used with caution. The mechanism of action of carbamates is similar to that of OPs, except that inhibition is by carbamylation and the reaction is slowly reversible and spontaneous. The most frequently used carbamate is carbaryl, which may be formulated with pyrethrins and/or synergists. These products are only approved for cats and dogs as shampoos (0.5% carbaryl) and dusts (12.5% carbaryl). Unfortunately, these products need to be applied more often than the newer generation of veterinary insecticides and insect resistance is commonly reported. Propoxur is another carbamate that is slightly more potent than carbaryl, but it is included in flea and tick collars for dogs and cats with claims of providing continuous protection against fleas for up to 5–6 months (e.g., Scratchex® for dogs). Toxicity associated with application of these two carbamates can be avoided if pets are not simultaneously exposed to anticholinesterase drugs or pesticides with similar mechanism of action and exposure is limited to cats and dogs older than 12 weeks.

d-Limonene and Linalool

These are volatile oil extracts from the peel of oranges, and it is their vapors, and not necessarily direct contact, that affects ectoparasites. This insecticide is formulated in shampoos and sprays. Although a relatively safe insecticide, **d-limonene** has caused *sporadic toxicoses* in cats (Hooser, 1990; Lee et al., 2002). Clinical signs are not often seen at the label concentration, but can occur at greater than five times the label dose. These signs can include excessive salivation, ataxia, and tremors as well as gross lesions in the scrotal and perineal area.

Amitraz

Amitraz is the only formamidine used in veterinary medicine, and is available in various formulations to treat for ticks, lice, and mites in dogs, swine, and cattle. To date, none of these approved products are labeled to repel or kill fleas. Although the mechanism of action of amitraz is not very clear, this ascaricide inhibits monamine oxidase (MAO) that normally metabolize neurotransmitter amines present in the CNS of ticks and mites. There are no effects on cholinesterase activity.

Efficacy

Amitraz is used as a dip (Mitaban®) to treat for generalized demodicosis (*Demodex canis*) in dogs. Amitraz can be applied as a 0.025% (250 ppm) sponge-on solution once a week (UK) or every two weeks (US). However, this drug is not approved to treat localized demodicosis or scabies. There are several reports describing the use of higher concentrations (e.g., 1.25%) or more frequent applications to treat for scabies (Hugnet et al., 2001). These off-label protocols run the risk of dogs developing severe signs of amitraz-related toxicosis described in Section Safety/Toxicity, and its advisable to use the more safe drugs described for this condition. For example, selamectin is the only approved spot-on drug for treatment and control of scabies in dogs (Shanks et al., 2000). Amitraz at 22.1% is formulated with fipronil (9.8%) and methoprene (8.8%) in a popular product called Certifect® for dogs. It starts killing all stages of ticks within 6 hours of application. It also aids in the control of sarcoptic mange infestations and by applying once per month for at least 2 months it is effective for the elimination of mites. Amitraz is also impregnated in tick collars for dogs (Preventic®, 9% active ingredient), and can kill ticks for up to 3 months with activity beginning within 24 hours of placing the collar on the dog. These amitraz tick collars are not approved for cats. Amitraz (e.g., Taktic® E.C., 12.5% active ingredient) is approved for use in beef and dairy cattle for ticks such as *Amblyomma americanum* and *A. maculatum*, mites such as *Chorioptes bovis, Psoroptes,* and *Sarcoptes scabei,* and biting louse (*Damalinia bovis),* and sucking lice *Haematopinus eurysternus, Lignathus vituli*, and Solenoptes capillatus. This product is also approved for use in swine to treat for mange mites and louse. Taktic® is not approved for use in horses or dogs as it may cause deaths!!! Once the spray mixture has been prepared it must be applied within 6 hours or it will lose its efficacy.

Safety/Toxicity

This drug is not approved for use in cats, chiuahuas, in pregnant or nursing bitches or puppies less than 3 months old (Curtis, 2004). In mammals, Amitraz activates α_2-adrenergic receptors, and adverse effects are similar to those seen with xylazine. Signs of toxicity include CNS depression, bradycardia, polyuria, hyperglycemia, and sedation, which can last for up to 24 hours

(Jones, 1990). Dogs tested with five times or 10 times the labeled dose usually develop most of these signs, therefore the final dip solution needs to be accurately prepared. The adverse effects from amitraz toxicosis can be reversed in dogs with a low dose of atipamezol (50 μg/kg IM), which is an α_2-antagonist (Hugnet et al., 1996). Accidental consumption of amitraz flea collars by dogs has resulted in toxicosis (Grossman, 1993). Swine should not be treated more than four times a year and should not be treated within 3 days of slaughter. Amitraz is a potential hazard to humans (Avsarogullari et al., 2006) if they do not wear appropriate personal protection such as chemical resistant gloves, aprons, and goggles/face shields.

Insect Growth Regulators (IGRs)

These agents first appeared in the market in the 1980s and 1990s, and were popular because the chemicals were promoted as not being a pesticide, and therefore harmless to the pet, livestock, and humans. The oral LD_{50} in rats for these chemicals range from 2 to 10 gram/kg body weight, which supports the extreme safety of these IGRs. These chemical agents affect the developing stages (eggs, pupae, and larvae) of insects and arthropods and do not affect the adult ectoparasite. Because of this, effective control is not achieved until several weeks after treatment and many of these IGRs are often formulated with adulticides described in this chapter. The IGRs can be grouped as juvenile-hormone analogs (JHAs) and insect development inhibitors (IDIs).

Juvenile-Hormone Analogs

The IGRs are juvenile hormone analogs, which falsely signal the organism such as ticks, fleas, and flies to *remain in its immature egg or larval stage* and not develop to adult stage. In the normally developing insect, the hormone levels usually decrease prior to the adult stage. The use of these JHAs therefore falsely signals to the developing insect to remain at its immature stage. Approved JHAs include methoprene, pyriproxifen, fenoxycarb, and cyromazine, with the former two JHAs being the most frequently used in veterinary medicine. Several of these JHAs are available as individual active ingredients in several topical formulations, but they are often formulated with adulticides such as the pyrethrins and/or pyrethroids. *Methoprene* is used mainly to control horn flies in cattle by incorporating it into the cattle concentrate (0.4%) or block (0.01%). This method of application prevents the emergence of adult horn flies from cattle manure. Methoprene is formulated with adulticides for premise flea control, and also formulated with fipronil, phenothrin, or permethrin for flea and mosquito control in dogs and cats. Some of these spot-on applications may contain as much as 2–3% methoprene. *Pyriproxyfen* is often applied as a spot-on, and is effective against flea eggs in cats for up to 56 days (Rust, 2005). This JHA applied every 3 months to cats can not only significantly reduce flea numbers but also 87% of the treated cats did not have fleas after 6 months (Maynard et al., 2001). As with methoprene products, pyriproxyfen is often formulated with adulticides such as permethrin, dinotefuran, and pyrethrins to be applied as sprays, spot-ons, and/or collars for cats and dogs.

Insect Development Inhibitors

The IDIs such as the benzoylphenyl urea compounds (*diflubenzuron, lufenuron*) interfere with the development of the insect exoskeleton by inhibiting chitin synthesis or deposition pathways. Chitin is an essential constituent of flea eggshells and exoskeleton of immature fleas. Following oral ingestion of *diflubenzuron*, it passes unchanged in the feces where it contacts the eggs and larvae of developing flies. *Lufenuron* (*Program*®) is administered orally at monthly intervals to cats and dogs to control fleas. There is also a subcutaneous injectable (10 mg/kg) for cats that is efficacious for up to 6 months against fleas. No adverse effects have been observed in cats, but injectable lufeneron should not be given to dogs as it causes adverse local reactions at the injection sites. As this drug is lipophilic, its slow release from adipose tissues allows maintenance of effective blood levels for several weeks after administration. One of the more popular IDIs is the combination of lufenuron and milbemycin oxime that is used to control fleas on dogs as well as a being a heart worm preventative.

Synergists and Repellents

Synergists such as piperonyl butoxide and *N*-octyl bicycloheptene dicarboximide (MGK 264) are often formulated with topical insecticide products to enhance the activity of insecticides. Almost all of the topicals formulated with these synergist contain pyrethroids and pyrethrins as the primary insecticide. These synergists inhibit oxidative and hydrolytic enzymes in the insects that are responsible for degradation of insecticides to harmless metabolites. It is believed that a carbene derivative forms and binds to the heme moiety of the cytochrome P450 enzyme making it inactive and unable to detoxify the insecticide. This then results in very high levels of the pyrethrin or pyethroid that are toxic and lethal to the ectoparasite (Murray and Reidy, 1989). Synergists by themselves are less toxic than the active ingredients in a topical formulation. Owners and veterinarians should, however, be aware that when cats are exposed dermally to synergists such as piperonyl butoxide at concentrations greater that 1.5%, this may similarly reduce detoxification of pyrethrins in cats and thereby also enhance toxicity of the insecticide in cats (MacDonald and Miller, 1986).

Repellents are also included in formulations to repel insects, although some repellents can be ectoparasiticidal such as permethrin, most repellents are not ectoparasiticidal. The primary advantage of the repellents is that they prevent transmission of vector-borne diseases even if these repellents are not ectoparasiticidal. A repellent can be effective via a number of mechanisms, including inability to enter or land on the hair coat, interfere with or inhibit feeding, and also cause the ectoparasite to become disoriented. Frequently used repellents include butoxypolypropylene glycol (Stabilene), di-n-propyl isocinchomeronate (MGK 326), and diethyl-m-toluamide (DEET).

DEET is an insect repellents approved by US EPA for use in dwellings, on the human body and clothing, on cats, dogs, horses, and pet living/sleeping quarters (US EPA, 1998). There are greater than 225 DEET products registered for use, with DEET concentrations ranging from 4% to 100%. However, DEET is not approved for direct application to the skin/coat of pets, and there are reports of adverse clinical signs in cats exposed to DEET topically (Dorman et al., 1990). Based on data from several experimental dermal absorption studies, DEET may influence the toxicity of insecticides by modulating insecticide dermal absorption (Baynes et al., 1997). Butoxypolypropylene glycol is usually formulated with a pyrethroid insecticide (e.g., resmethrin, permethrin) and/or a synergist (e.g., piperonly butoxide). Most of these formulations are approved for use in horses, cats, and dogs, and formulated as sprays with concentrations ranging from 4.8% to 20%. No adverse effects in pets or laboratory animals have been attributed to this repellent (CA EPA, 2002). MGK 326 is often formulated with pyrethroids and/or synergist to be used as sprays, dips, and shampoos in horses, dogs, and cats. Another safe product, Centaura^{TM} Insect Repellent, which contains 20% picardin, claims to provide 12-hour protection from flies, mosquitoes, and ticks for horses and riders.

Ectoparasiticide Approval and Registration in the US

Unlike other drug classes discussed in this book, either the US EPA or the US FDA Center for Veterinary Medicine (CVM) is involved in the approval of ectoparasiticides. The US FDA CVM evaluates those chemicals that are administered orally or topically but exert their effects following systemic distribution. These chemicals are classified as drugs and many of these drugs require a veterinary prescription. The US EPA evaluates those chemicals applied topically, but exert their effect on the surface of the skin or around the farm premises, and do not often require a veterinary prescription. Table 43.5 summarizes the differences in function between these two critically important federal agencies in the USA.

In spite of these clear distinctions, there is still confusion amongst pet owners and even some veterinarians about how flea products are marketed in the USA as some products can be obtained over-the-counter (OTC) in pet and feed stores while others can only be obtained from the veterinarian. The latter is often referred to as the veterinary-channel products (e.g., Fipronil and Imidacloprid). Even though those flea products may not require a prescription, obtaining these products from a veterinarian only ensures that a client–patient–veterinarian relationship is established, which reduces the probability of

Table 43.5 Comparisons of USFDA CVM and US EPA with regards to ectoparasiticides

	US FDA CVM	US EPA
Mission	Approval and effects of drugs and feed on animals Company files a New Animal Drug Application (NADA) to FDA	Preserve and improve quality of the environment and human health Registration of pesticides Company files an Application for Pesticide Registration (APR) to EPA
Scope	Concerned with drugs that work systemically in the animal This includes any route of administration to the animal	Concerned with anything that affects air, water, and soil quality Chemicals that are applied topically to animals but not absorbed systemically
Safety studies requirements for FDA approval or EPA registration	Drug formulations must be evaluated in same species for which the drug is designated	Active ingredients are tested in lab animals Formulations do not have to be tested in the designated species
Efficacy	Flea control products must be at least 90% efficacious Clinical studies required	Clinical studies not required Practical efficacy in market place is required
Drug distribution	Often by prescription from a licensed veterinarian	Often sold over-the-counter at retail outlets

insecticide toxicoses often associated with OTC products used by pet owners. As discussed in various sections of this chapter, this has often been the problem with OTC pyrethroid and OP products used in cats and dogs.

Another issue that is of concern to the federal government is the extralabel use of ectoparasiticides. The passage of the Animal Medicinal and Drug Use and Clarification Act (AMDUCA) in 1994 allows but does not encourage the extralabel use of approved animal or human *drugs* in special circumstances. As pesticides are not approved drugs, extralabel use of these chemicals is not covered by AMDUCA and extralabel use is strongly prohibited.

Chemotherapy of Neoplastic Diseases

Luke A. Wittenburg and Daniel L. Gustafson

The current era of chemical anticancer therapy took hold in the mid-20th century, yet its roots can be traced back 50 centuries to ancient descriptions of neoplastic diseases and the use of medicinal herbs and botanicals in the treatment of these conditions (Papac, 2001; DeVita and Chu, 2008; Morrison, 2010). Nitrogen mustard, the first modern pharmacological chemotherapeutic agent, was developed in the 1940s and additional drugs derived from nitrogen mustard followed shortly after (DeVita and Chu, 2008). The first reported case of treatment of cancer in veterinary medicine occurred in 1946 and involved the use of urethane to treat a dog with lymphoma and lymphocytic leukemia (Innes et al., 1946). The first facility devoted entirely to the treatment of cancer in dogs, the Canine Cancer Clinic, was founded in 1950 and within 10 years had published a review of chemotherapy treatment of spontaneous cancers in canines using numerous agents ranging from nitrogen mustards to cortisone (McCoy, 1958; Morrison, 2010). It was suggested as early as 1962 that the treatment of animal cancer patients had become an obligation of the veterinarian to his or her community (Morrison, 2010). With the advent of animal models of cancer that were predictive for antineoplastic drug activity, drug screening programs were initiated in the 1950s that ultimately resulted in the discovery and development of many of the agents in clinical use today. Since that time, significant advances have been made in the understanding of the biology of cancer and response of specific tumor types to various drugs. While direct translation of discoveries made in human oncology has been hampered, in part by species differences in drug pharmacokinetics, expense, and lack of widespread availability of adequate supportive care in general practices, there has been a significant improvement in the quality, and in many cases quantity, of life for pet cancer patients through improved client education and rational decisions in the selection of appropriate patients while matching therapeutic regimen with therapeutic goal.

Terminology and Treatment Perspectives

Chemotherapy is defined as the application of drugs in an attempt to kill or inhibit the growth of viruses or foreign cells such as bacteria or fungi in the body. Although originating from the individual, cancer cells are viewed as “foreign” in this sense. Recent advances in understanding the biology of cancer and cellular signaling networks important in cancer cell survival and proliferation have led to the development of *targeted therapies*, usually small molecules or antibodies directed at specific cellular receptors or proteins. In contrast to these therapies directed at tumor cells, cancer *immunotherapy* can have an indirect action through potentiation or reactivation of antitumor immune responses that tumors often suppress as a means of escaping immune recognition. Regardless of the type of therapy employed, the treatment regimen chosen must be appropriate for the therapeutic goal for the individual patient. A *cure* is defined as the complete eradication of all tumor cells within the body; in most cases this is not achievable and *palliation,* the reduction of pain and improvement of function to enhance quality of life in the absence of a possibility of cure, has become increasingly recognized as an acceptable therapeutic goal.

The ratio of the toxic dose to the therapeutic dose of a drug is termed the *therapeutic index*. This is often extremely small in cancer chemotherapy as the dose that causes a desired effect, such as reduction in tumor size, is often anticipated to cause some degree of toxicity. Furthermore, the vast majority of chemotherapy drugs are administered at the *maximum tolerated dose* (MTD) which is defined as the highest dose of a drug that can be given without unacceptable or irreversible adverse events and is generally empirically derived in a small population of animals. Toxicities following drug administration in veterinary patients is scored based on guidelines set forth in the Veterinary Co-operative Oncology Group Common Terminology Criteria for Adverse Events

Veterinary Pharmacology and Therapeutics, Tenth Edition. Edited by Jim E. Riviere and Mark G. Papich.

(VCOG-CTCAE) (VCOG, 2011) and are used to guide dose adjustments for subsequent treatments. More recently, the advent of targeted therapy has given rise to the concept of a *biologically effective dose* (BED), defined as the dose leading to some measurable desired response at the proposed target or a surrogate biomarker. Dosing of chemotherapy drugs in humans and animals is generally based on body surface area (mg/m^2) instead of patient weight (mg/kg). This was originally instituted as a means of normalizing the maximum tolerated dose of drug between species and was based on the idea that physiological processes that influence drug activity in the body correlate better with body surface area than weight. The exception to body surface area based dosing in veterinary medicine is in very small patients where this dosing results in a relatively higher dose and often weight based dosing may be chosen for animals weighing less than 10 kg. The formula for converting weight to body surface area for dogs and cats is:

$$Surface\ Area = \frac{Body\ Weight^{0.67} \times K}{10^4}$$

where surface area is given in square meters and K is a species constant with a value of 10.0 and 10.1 for cats and dogs, respectively. Numerous tables exist for conversion of weight to surface area.

The decision to use a certain chemotherapeutic drug or combination of drugs, with or without additional therapeutic modalities such as surgery and radiation therapy, as well as the assessment of response, is influenced by the therapeutic intent for each individual patient. Therapeutic decisions are influenced by patient factors such as species, breed, age, and health status, neoplasm factors such as histological type, stage and/or grade of tumor, facility factors such as availability of quality follow-up care and available treatment modalities, and pet owner factors such as time commitment, tolerance for adverse effects, and cost of therapy.

Adjuvant therapy, where chemotherapy is utilized following control of the primary tumor by means such as surgery or radiation, aims to limit the spread of micrometastatic disease and is a common application of chemotherapy in veterinary medicine. *Neoadjuvant* or *primary therapy* is the use of chemotherapeutic drugs prior to surgery or radiation as a means of limiting spread of metastatic disease as well as reducing primary tumor burden. In reference to hematopoetic or lymphoid tumors, *induction therapy* is a term referring to the initial utilization of chemotherapy drugs to induce a remission. Following induction of remission, *maintenance therapy* involves the use of chemotherapy with the goal of maintaining a stable remission. When a tumor fails to respond to chemotherapy or a patient comes out of remission, *rescue* or *salvage therapy* is often employed with the goal of achieving a second remission.

Cancer Biology

A basic understanding of some of the aspects of the biological behavior of cancer is important for understanding the therapeutic approaches and the limitations of these approaches due to the striking diversity of neoplastic diseases. The transformation of normal cells to neoplastic cells can be viewed as a multistep process by which normal cells acquire successive capabilities that allow for tumor growth and subsequent spread throughout the body. These capabilities have been described as “hallmarks” of cancer and are traits that differentiate cancer cells from normal cells in the body, the most fundamental being the ability to sustain signaling that allows the cell to continuously proliferate (Hanahan and Weinberg, 2011). In addition to sustaining positive proliferative signaling, cancer cells must also bypass the programs that are designed to inhibit proliferation and maintain homeostasis of cell numbers and normal tissue architecture through control of entry into the cell growth and division cycle (Hanahan and Weinberg, 2011). While the biochemical processes of cell proliferation and passage through the cell cycle are the same between cancer and normal cells, it is the rate and timing of the processes that provide a qualitative difference and results in the utilization of drugs that target rapidly dividing cells as a therapeutic option. Because many of the drugs are most active against cells that are actively dividing, and some chemotherapy agents are more active in specific phases of the cell cycle, an understanding of the activities that occur during each phase of the cell cycle is important. The cell cycle is generally divided into four phases: G_1, S, G_2, and M, with cells that are at rest or not actively dividing termed G_0. The G_1 phase is a period of cell growth, active gene transcription, and protein synthesis and is required for building up the “biomass” required for cell division. This phase is followed by the S phase, a period of DNA replication and chromosome duplication in preparation for mitosis. During the G_2 phase the cell continues to grow in size and in M phase the cells undergo active mitosis. Prior to the start of the S and M phases of the cycle are two important checkpoint mechanisms, which cells utilize to ensure that the cell is prepared to carry out chromosome duplication and mitosis, and these checkpoints are often bypassed in cancer cells allowing for uncontrolled growth. Figure 44.1 depicts the cell cycle specificity of the major classes of drugs that are used in veterinary medicine. Other hallmarks of cancer have also provided some potential therapeutic targets. While sustaining positive proliferative signaling and evading growth-suppressive signaling are important for cancer on the cellular level, in order to grow into a clinically relevant mass a tumor must induce angiogenesis, or the formation of new vasculature, in order to provide for the increasing demand for nutritional support (Folkman,

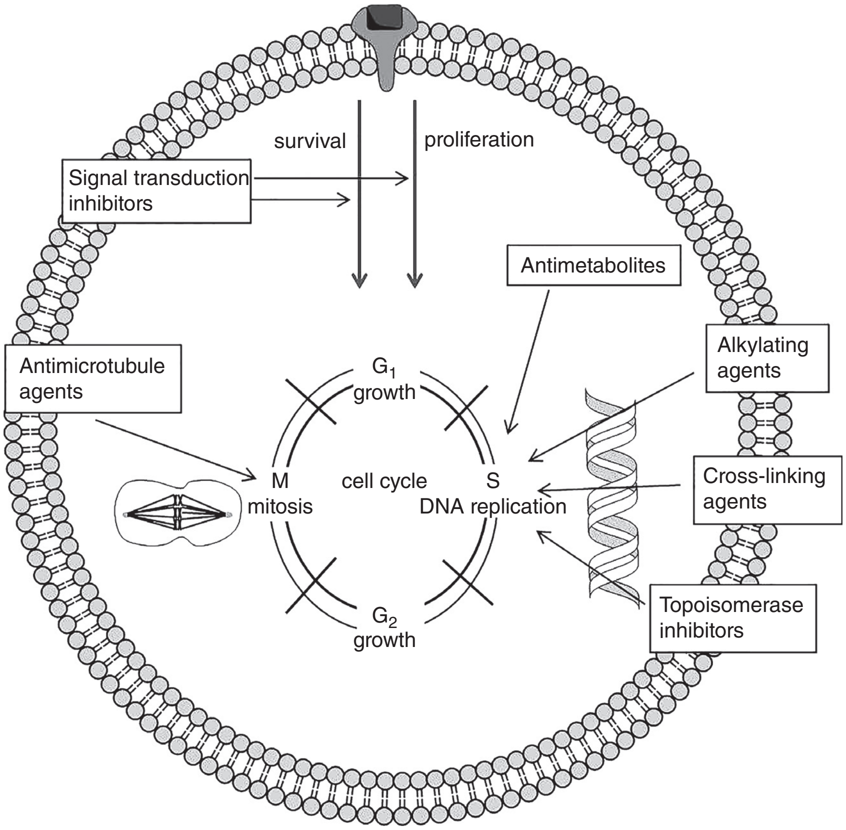

Figure 44.1 Cellular targets of the common classes of chemotherapeutic agents used in veterinary oncology and their sites of activity.

2002). Targeting tumor vasculature has been proposed as a way to control tumors by effectively starving them to prevent further growth (Kerbel and Folkman, 2002). The term *metronomic chemotherapy* refers to the use of low-dose, continuous administration of conventional cytotoxic drugs without breaks in treatment and has been utilized successfully in human and veterinary oncology as a means to delay tumor recurrence or slow growth (Elmslie et al., 2008; Burton et al., 2011; Romiti et al., 2013; Schrempp et al., 2013).

While uncontrolled cellular growth and passage through the cell cycle are a hallmark of cancer cells, the growth rate of a tumor in the clinical setting does not necessarily directly correlate with the rate at which cells are traversing the cell cycle. Early studies into the kinetics of cell proliferation in experimental tumors demonstrated that tumor growth rate is rapid initially but then slows as the fraction of cells entering the cell cycle reduces and cell death increases, potentially due to reduced availability of nutrient supply in bulky tumors; in each examined stage of tumor growth the length of the cell cycle itself remained unchanged (Frindel et al., 1967). Clinically, many tumors in veterinary medicine are diagnosed when they are relatively advanced and thus there may be only a small fraction of cells that are actively undergoing cell division, which has implications for effectiveness of therapy when utilizing drugs that have their maximal effect on actively dividing cells. In the 1960s, studies in mice utilizing leukemia cell lines demonstrated that a single cell was capable of generating a tumor and that a cure could only be attained by eradication of all tumor cells (Skipper et al., 1964). Furthermore, it was determined that any effective dose of chemotherapy killed cells by log kill kinetics, which led to the *fractional kill hypothesis*. This states that with each dose of chemotherapy a constant fraction of cells is killed, as opposed to a constant number of cells, regardless of the size of the original tumor and that successful therapy is then dependent upon the number of cells present at the beginning of treatment. Thus, in theory, with the application of multiple doses of chemotherapy it should be possible to attain a cure. In practice this is not always the case as the fraction of cells killed with many of the available drugs is small, resistance to therapy often occurs, and toxicities prevent rapid successive administration of drugs. However, these concepts illustrate the importance of early detection in a successful treatment outcome as smaller tumors are likely to have a larger dividing fraction and the fractional kill hypothesis implies that a cure could be achieved earlier in the course of treatment for smaller tumors with fewer cells present.

Chemotherapy of the Cancer Cell

Tumor Cell Sensitivity

Increased understanding of cancer cell biology has led to the evaluation of a number of novel targets for therapy. The targets for traditional cytotoxic chemotherapy include DNA (through targeting of nucleotide bases, enzymes involved in DNA synthesis, and DNA damage repair), microtubules, and growth factor receptors. More recently discovered targets include products of overexpressed oncogenes, antiapoptotic proteins, cell-cycle regulators, proteasomal machinery, cell surface antigens, and enzymes involved in epigenetic modulation of DNA. While cancer in veterinary patients may share many of the same putative targets as human cancers, translation of newer "targeted" therapies into veterinary medicine has lagged behind development in human oncology, with a couple of notable exceptions. This chapter will focus on the drugs that are currently in primary use for veterinary oncology.

Individual cell sensitivity to a drug is dependent upon a number of factors, such as absorption, distribution, and metabolism, entry into the cell or affinity of interaction with a cell-surface target, the type of lethal or sublethal damage induced, and the cellular response to this damage. Altered tumor vasculature and differences in intratumoral pressure or drug binding can affect drug uptake in a negative or positive way. Some drugs can enter the cell through passive diffusion due to the lipophilic nature while others may utilize active transport via an array of carriers such as amino acid transporters (melphalan), nucleoside transporters (gemcitabine), or reduced folate carriers (methotrexate)(Goldman et al., 1968; Mackey et al., 1998; Yanagida et al., 2001). The importance of active transport mechanisms for entry into the cell is that reduced entry, and thus diminished efficacy, can occur with administration of other substrates or analogs that block drug transport. Many cytotoxic drugs exhibit greater toxicity in rapidly dividing cells and are termed *cycle specific.* There are a few drugs that have similar effects on proliferating and nonproliferating cells, including the nitrosureas (cyclohexylchloroethylnitrosourea, CCNU, and bischloroethylnitrosourea, BCNU)(Twentyman and Bleehen, 1975). Because they do not require cells to be proliferating to exert lethal effects these drugs are termed *cycle nonspecific.* Other cytotoxic drugs may demonstrate variations in lethal toxicity depending on the phase of the cell cycle and are termed *phase specific.* Vinca alkaloids and taxanes are examples of drugs that exert lethal damage exclusively in cells undergoing mitosis as they target the dynamics of microtubule formation. For drugs that have a very direct and specific interaction with a target molecule, the cellular levels of the target can affect the intrinsic sensitivity of the cell. For example, doxorubicin and other anthracyclines interact with topoisomeraseII-α (TopoII) and reduced levels of this target have been identified in populations of doxorubicin-resistant cells (Withoff et al., 1996). Furthermore, amplification of the gene encoding TopoII, leading to increased target expression, has been identified as a potential marker of enhanced sensitivity and improved outcome with anthracycline-based chemotherapy in human breast cancer patients (Park et al., 2003). For drugs that directly target DNA, the sensitivity of a cancer cell is dependent upon the balance between formation of DNA lesions and repair of the lesions. Alkylating agents such as cyclophosphamide exert their toxic effect by inducing DNA strand breaks following the formation of O'6-methylguanine; the enzyme O'6-methylguanine-DNA methyltransferase (MGMT) is a conserved protein that is capable of directly reversing this lesion and levels of MGMT have been proposed as a predictor of tumor sensitivity to alkylating agents in humans (Hansen et al., 2007; Xu et al., 2014). Often, the final effector of cancer cell death following exposure to cytotoxic drugs is the activation of apoptosis, or programmed cell death. The activation of apoptosis in a cell following a toxic insult is dependent upon the balance of pro- versus antiapoptotic signaling, and alterations that shift the balance in the direction of antiapoptosis, as has been demonstrated in human and canine lymphoma with elevated levels of the antiapoptotic protein survivin, have a negative impact on chemosensitivity (Ambrosini et al., 1997; Rebhun et al., 2008). Thus, the proximity of a cancer cell to the "apoptotic threshold", determined by the interplay between the pro- and antiapoptotic signals, can be a key determinant of therapeutic responsiveness.

Currently, there are efforts to utilize the in vitro chemotherapeutic sensitivity of large panels of cell lines, such as the NCI 60, along with gene expression data from these cells, to begin to build models that might predict sensitivity of other cell and tumor types based on similarities in gene expression signatures, and validation of these models may allow the future administration of cytotoxic agents in a more personalized manner (Scherf et al., 2000; Lee et al., 2007).

Tumor Cell Resistance

Resistance to chemotherapy is the major mechanism of therapeutic failure in cancer drug therapy. Many of the hallmarks of cancer and the genetic instability of cancer cells provide mechanisms whereby cells can tolerate and sustain the stresses induced by cytotoxic drugs. Resistance can be either intrinsic to the cell or acquired through the selection and subsequent expansion of resistant clones as sensitive cells are killed. Intrinsic resistance mechanisms are those that are constitutively expressed in the tumor tissue from the outset of therapy as they are generally derived from the normal tissue from which the tumor developed. As a component of their barrier function, epithelial tissues generally express numerous transport and detoxifying enzymes for xenobiotics, and carcinomas derived from these tissues also often express increased levels of these enzymes leading to a more resistant phenotype. Conversely, tumors derived from normal tissues with lower levels of defense mechanisms, such as hematopoietic or lymphoid tissues, are relatively more chemosensitive than epithelial tumors. As mentioned in the previous section, altered drug uptake can influence the sensitivity or resistance level of a cancer cell to drugs such as melphalan, methotrexate, or nucleoside analogs such as gemcitabine. Some cytotoxic agents are administered as prodrugs and require metabolic or catabolic activation to an active form to result in cell death. Reduced activation has been identified as a potential mechanism of acquired resistance for the nucleoside analog group of drugs and has been suggested as a mechanism for resistance to the alkylating agents cyclophosphamide and ifosfamide (Spears, 1995; Zhang et al., 2005). When administered as single agents, that is not as part of a combination therapy protocol, resistance to some drugs manifests as a direct modification of the drug target. Resistance to antimetabolite drugs such as methotrexate and 5-fluorouracil has been found to involve either direct mutation of the target enzyme that reduces binding affinity or mutation that results in decreased levels of the target directly (Gonen and Assaraf, 2012). Similarly, target-based mechanisms of resistance have been identified for the microtubule binding drugs such as taxanes, vincristine, and vinblastine. As these drugs disrupt normal tubulin dynamics through their interaction with β-tubulin, increased expression of different cellular isoforms of β-tubulin with lower binding affinity has been identified, as has mutation in the target β-tubulin that also results in reduced binding affinity (Monzo et al., 1999; Rebucci and Michiels, 2013). For the group of drugs that target DNA replication through interactions with topoisomerase I or II, mutations in the gene encoding the topoisomerase enzyme have been identified, and cells with reduced levels of topoisomerase II demonstrate resistance to doxorubicin (Pilati et al., 2012; Tomicic and Kaina, 2013).

In addition to qualitative and quantitative alterations in the interaction of cytotoxic drugs with their targets, resistance can also develop through increased metabolism or detoxification of a drug by cancer cells. Many of the currently used cytotoxic agents interact with DNA through electrophilic interactions, making them sensitive to thiol-mediated inactivation by conjugation with nucleophiles such as glutathione (Tew, 1994). Induction of the enzyme responsible for conjugation of glutathione to cytotoxic drugs, glutathione S-transferase (GST), has been demonstrated in leukemia cells that have acquired resistance to alkylating agents and there is evidence that this may also be a mechanism through which tumors can acquire resistance to platinum agents such as cisplatin (Schisselbauer et al., 1990; Tew, 1994). In addition to detoxification through conjugation, metabolic inactivation of drugs is implicated as a mechanism of resistance in some instances. Acquired resistance to the nucleoside analog 5-fluorouracil can be associated with elevated cellular levels of dihydropyrimidine dehydrogenase (DPD), the main enzyme responsible for metabolism of fluorouracil to an inactive compound, and DPD activity in tumor tissue has been utilized as a potential marker in determining whether a particular tumor is likely to demonstrate resistance to therapy (Baba et al., 2003; Rebucci and Michiels, 2013).

As the cellular target of many cytotoxic agents is ultimately the DNA, alterations in the response to DNA damage will determine the fate of the cell exposed to these drugs. In normal cells, the DNA damage response is intimately related to cell cycle progression, and detection of damaged DNA generally leads to cell cycle arrest to allow for repair or, if damage cannot be repaired, apoptosis. Resistance to cytotoxic agents can occur through up-regulation of DNA repair processes that abrogate the effects of DNA damaging agents or through down-regulation of damage recognition, both of which act to prevent induction of apoptosis. Altered activity of repair processes specific to double-strand breaks, single-strand breaks, single-nucleotide excision, and base mismatch repair have all been found to play some role in the acquired resistance to a diverse group of cytotoxic agents, including the anthracyclines, camptothecins, alkylators, and platinum agents (Parker et al., 1991; Fink et al., 1998; Pommier et al., 1999; Martin et al., 2008; Helleday, 2010). Some general mechanisms of acquired resistance to cytotoxic agents are listed in Table 44.1.

Table 44.1 General mechanisms of acquired resistance leading to therapeutic failure for some cytotoxic agents

Mechanism	Drugs/classes involved
Reduced uptake	Methotrexate, gemcitabine, cisplatin, melphalan
Increased efflux	Doxorubicin, vinca alkaloids, taxanes
Decreased activation	Antimetabolites (nucleoside analogs)
Increased or decreased levels of drug target	Doxorubicin, methotrexate
Target mutations/reduced binding	Vinca alkaloids, methotrexate
Drug inactivation/ detoxification	Alkylating agents, cisplatin
Increased damage repair	Alkylating agents, cisplatin, doxorubicin
Intracellular redistribution of drug	Doxorubicin

Table 44.2 Examples of ABC transporters implicated in MDR and cytotoxic agents identified as substrates

Transporter	Substrates
MDR1	Doxorubicin, vinca alkaloids (vincristine, vinblastine), taxanes, methotrexate, mitomycin C, epipodophyllotoxins
MRP1	Doxorubicin, vinca alkaloids, paclitaxel, mitoxantrone
MRP2	Cisplatin, vinca alkaloids, doxorubicin, mitoxantrone, methotrexate
BCRP	Mitoxantrone, camptothecin, methotrexate, etoposide, doxorubicin[a], methotrexate[a]

[a] Identified as substrates for mutated forms of the protein but not wild-type (Meyer et al., 2011).

ABC, ATP-binding cassette; BCRP, breast cancer resistance protein; MDR, multiple drug resistance; MRP, multidrug resistance-associated protein.

One very concerning mechanism of acquired resistance results in a phenotype in which cancer cells become resistant to a variety of structurally and mechanistically diverse drugs. While alterations in DNA repair processes or detoxification via glutathione conjugation can certainly lead to resistance to more than one drug, the classic mechanism resulting in the multiple drug resistance (MDR) phenotype involves the increased removal of drugs from the cell. This is more commonly encountered following therapy with multiple drug protocols where resistance does not appear to occur simply through a combination of target-directed alterations that confer resistance to the individual components of the protocol, but through a more global phenotypic change toward chemoresistance (Pritchard et al., 2012). The MDR phenotype generally refers to the increased expression of energy-dependent integral membrane transport proteins that function to remove drugs from the cell following exposure to chemotherapy (Table 44.2). The major family of proteins that has been implicated is the ATP-binding cassette transporter (ABC) family, comprising approximately 48 proteins, of which 15 are known to have chemotherapeutic drugs as substrates (Fletcher et al., 2010). The most well studied of these proteins is P-glycoprotein, a product of the MDR1 gene (*ABCB1*), which has been implicated in resistance to a number of lipophilic cytotoxic drugs including the vinca alkaloids, anthracyclines, epipodophyllotoxins, taxanes, actinomycin D, topotecan, methotrexate, and mitomycin C (Fletcher et al., 2010). Aside from being expressed in some tumor tissues, *ABCB1* is also expressed in normal cells that line tubules and ducts, serving a role that allows for removal or prevention of uptake of xenobiotics into these cells. Tissues such as kidneys and adrenals, liver and pancreas, endothelial cells (particularly those of the blood–brain barrier), small intestine and colon, and testes all express varying levels of *ABCB1*. Therapeutic implications of the expression of *ABCB1* in nontumor tissues include reduced absorption of orally administered substrates requiring intravenous administration to achieve effective levels and hastening the elimination of substrates from the kidney and liver. Importantly, a loss of this normal barrier function has been demonstrated to result in increased toxicity from substrate drugs such as that seen in Collie dogs and related breeds following exposure to ivermectin or loperamide manifesting as neurotoxicity (Mealey et al., 2001; Sartor et al., 2004). In addition, increased toxicity of substrate chemotherapeutic drugs has been identified in the same population even at reduced doses (Mealey et al., 2003), and pharmacokinetic modeling suggests that this population of dogs may not be able to safely receive substrate drugs such as doxorubicin at doses that are tolerable yet retain efficacy (Gustafson and Thamm, 2010). A more complete review of the therapeutic implications of the MDR1 gene has been published previously (Mealey, 2004) and is discussed in Chapter 50.

The other ABC transporters that have been studied the most extensively with regard to a role in acquired resistance to chemotherapy are the BCRP (*ABCG2*), MRP1 (*ABCC1*), and MRP2 (*ABCC2*) proteins (Wu et al., 2011). The importance of these transporters has been less extensively studied and their importance in the MDR phenotype in veterinary cancer therapy is less well defined. Another transporter that does not belong to the classical ABC family of membrane proteins has been implicated in resistance through redistribution of drug within the cell resulting in accumulation away from the target. The major vault protein (MVP/LRP) has been found to cause sequestration of anthracycline drugs within cytoplasmic organelles preventing their interaction with topoisomerase enzymes (Kickhoefer et al., 1998). Clinical studies from human oncology have attempted to address MDR in cancer through administration of various inhibitors of ABC transporters, most often ABCB1; however, results have been disappointing and explanations for these results include the functional redundancy of some transporters in addition to the fact that often more than one is up-regulated, as well as an increase in systemic toxicity most likely due to altered pharmacokinetics with regard to reduced clearance mechanisms (Fletcher et al., 2010).

Combination Chemotherapy

Veterinary cancer patients may frequently be treated with a combination of chemotherapy drugs or with multimodal therapy, which combines chemotherapy with other modalities such as surgery or radiation therapy. Combination therapy mainly provides a mechanism whereby tumors are exposed to increased dosages of drug which subsequently provides for increased fractional cell kill. The term *summation dose intensity* (SDI) is used to express the relationship between the number of agents in a combination and the overall dose, and can be increased through either adding more agents to the combination or increasing the dose of individual agents. For a combination chemotherapy protocol to provide a therapeutic advantage, the increased toxicity to cancer cells must be greater than any increase in damage to critical normal tissues. The implementation of combination therapy in clinical practice is based in the early studies of leukemia models in mice, which were then translated into treatment of childhood leukemia and resulted in the first major improvements in both the rate and duration of remission and resulted in the first responses that were compatible with a cure (Law, 1952). One of the driving factors in development of combination therapies relates to heterogeneity within tumors with regard to cytokinetics; with a tumor mass containing both cycling and noncycling cells, the use of cycle-specific agents to kill mitotically active tumor cells and cycle nonspecific agents to kill noncycling tumor cells was empirically employed. Furthermore, the reduction of tumor mass using cycle nonspecific drugs may actually increase the growth fraction of a tumor through various mechanisms and increase the sensitivity to cycle-specific drugs (Frei and Antman, 2000). The rational development of combination protocols is based on a number of factors, such as independent or nonoverlapping toxicities, allowing for use of each drug at a full dosage, and each component of the combination should demonstrate some degree of efficacy when used as a single agent. In addition, use of drugs with nonoverlapping mechanisms of action and resistance may provide an improved therapeutic benefit when used in combination. Consideration should be given to the schedule of drug administration (i.e., the order in which drugs are given and timing between drugs) in combination therapy as the effects of the schedule can be quite substantial, although it is less well understood than the effects of dose. The best studied example of the superiority of combination therapy in veterinary oncology is in the treatment of lymphoma in dogs, in which combination protocols provide an improved response rate and duration of first remission when compared to numerous single-agent protocols (Chun, 2009).

Pharmacodynamic Response

With regard to cytotoxic chemotherapy protocols, pharmacodynamic considerations relate to standard measures of response and in veterinary medicine have been adopted from the Response Evaluation Criteria in Solid Tumors (RECIST) guidelines used in human oncology (Eisenhauer et al., 2009). Terms that are important in the clinical evaluation of cancer therapeutics involve measurements of tumor shrinkage and tumor burden versus disease progression:

Complete response (CR): complete disappearance of all target lesions and resolution of symptoms of disease.

Partial response (PR): decrease in the volume of target lesions by 50% or decrease in the maximum diameter of >30%.

Stable disease (SD): neither an increase nor decrease in tumor size or disease symptoms (>20% change in tumor diameter).

Progressive disease (PD): increase in tumor volume of >25% or increase in maximum diameter of >20% *or* appearance of new lesions.

Median duration of response/survival (MDR/MDS): median value for a group of animals treated with a given therapy in terms of the length of time they achieved a complete or partial response or length of survival following initiation of therapy.

Progression-free interval/progression-free survival (PFI/PFS): the amount of time elapsed without evidence of either progressive tumor growth (PFI) or survival without progressive growth of tumor measured from the time of initiation of therapy (PFS).

Disease-free interval/disease-free survival (DFI/DFS): the amount of time elapsed without any disease recurrence (DFI) or the duration of survival of the patient following initiation of therapy (DFS).

With the introduction of newer targeted agents in veterinary medicine, pharmacodynamic responses can also be evaluated by detection of direct inhibition of the molecular target. Studies of the c-KIT inhibitor toceranib have demonstrated that, when used at clinically effective doses, reductions in the amount of activated KIT protein can be detected and these changes correlate with the plasma concentrations of drug (Pryer et al., 2003). Identification of these types of biomarkers of drug activity and their correlation with plasma concentrations may become more important as the optimal dosing of these types of targeted therapies may not be based on MTD but on the biologically effective dose required to inhibit a molecular target.

Drug Toxicity

Aside from the determinants of sensitivity and mechanisms of resistance described above, failure of a given therapeutic protocol may also be a result of treatment discontinuation due to unacceptable toxicity. Phase I studies specific to companion animals for a number of cytotoxic agents have been performed and the MTD defined from these studies is generally the suggested starting dose. However, there is substantial inter- and intraindividual variability with regard to efficacy and toxicity following equivalent doses in patients. For example, in human patients following standard doses of some drugs the variability in drug exposure can range between two and tenfold (Masson and Zamboni, 1997). The pharmacokinetic parameters of many anticancer agents are associated with outcome in terms of response and toxicity, and the high degree of variability makes for inaccurate predictions of response based solely on dose administered. A complete review of the reasons for pharmacokinetic variability in cancer is beyond the scope of this chapter, but patient variability with regard to PK and patient physiology and altered physiological states has been reviewed elsewhere (Undevia et al., 2005; Martinez and Modric, 2010; Modric and Martinez, 2011).

With a few drug-specific exceptions, cytotoxic chemotherapy drugs generally produce a characteristic set of toxicities to various tissues that are often related to the tissue growth rate; given appropriate time most if not all of these tissues will recover. In fact, current convention of scheduling in combination protocols is determined by the length of time it takes for normal tissues to recover following cytotoxic insult. In addition, it is the development of improved supportive care procedures that often allows for more dose-intense treatment protocols. Thus, the selective therapeutic advantage of "nontargeted" or general cytotoxic agents lies in the fact there is often more rapid and complete repair of damage in normal cells than cancer cells.

Toxicities that develop following chemotherapy administration can be placed into three categories: (i) acute toxicity that generally occurs during treatment or very shortly thereafter, (ii) acute-delayed toxicity which generally occurs within 2–14 days following administration, and (iii) chronic or cumulative toxicity that can develop anywhere from weeks to years following administration. Acute toxicity can manifest as hypersensitivity reactions that occur during infusion and result from histamine release caused by either the active drug (L-asparaginase, doxorubicin) or from vehicle-mediated mast cell degranulation (paclitaxel and etoposide). Treatment of this hypersensitivity often involves stopping administration of the drug and general symptomatic therapy for allergic reactions and anaphylaxis such as antihistamines and/or steroids. Routine pretreatment with antihistamines in patients with known hypersensitivity to a given drug may also be effective in preventing acute reactions. Acute reactions may also present as nausea and vomiting that can be intrinsic to the drug (cisplatin) or a function of a rapid rate of infusion (doxorubicin). Pretreatment with antiemetic drugs and increasing length of infusion can be effective means to prevent acute vomiting. Examples of potential cumulative/chronic toxicities include dilated cardiomyopathy in dogs when cumulative doxorubicin doses exceed 180 to 240 mg/m^2, hepatic dysfunction following administration of CCNU, and renal failure following cisplatin use in dogs or doxorubicin in cats. It is important to understand that these toxicities could potentially develop after only a single administration and thus do not always present following chronic administration or follow a protracted course of appearance.

Careful evaluation of clinical and laboratory indices prior to administration and careful monitoring during treatment, as well as prudent choice of drug, are critical in preventing or reducing severity of these toxicities. Secondary malignancies are reported for some of the cytotoxic agents due to their mitogenic potential following DNA damage. This is not commonly encountered in veterinary medicine as the length of time between drug administration and the development of a secondary malignancy is often longer than most pets survive. Here again there are differences in the ability to cause secondary malignancies between drugs with the alkylating agents being the most mutagenic and vinca alkaloids among the least mutagenic. The delayed acute effects are most commonly encountered following cytotoxic chemotherapy and some degree of these effects is generally expected. Tissues that seem to be particularly affected following the majority of cytotoxic agents include bone marrow, gastrointestinal mucosa, gonads, and hair follicles (tissues in which cells require constant renewal due to a short lifespan). Lymphocytes and bone marrow cells appear particularly sensitive to cytotoxic agents and neutropenia is often the dose-limiting toxicity (DLT). The low point in neutrophil count following chemotherapy is referred to as the *nadir* and is generally thought to occur 7–14 days following treatment with most drugs. Severe neutropenia can adversely affect treatment as it can result in dose reductions, treatment delays, and sepsis. Careful monitoring of leukocyte count is critical for appropriate management of neutropenia with regard to appropriate supportive care and future dose determination. Consideration of drugs used in combination protocols must account for the propensity of specific drugs to result in neutropenia as some drugs are more prone to result in significant myelosuppression (cyclophosphamide, carboplatin, doxorubicin, CCNU, vinblastine) while others may cause minimal neutropenia (bleomycin, vincristine in dogs, L-asparaginase). In cases of severe myelosuppression the administration of a recombinant granulocyte-colony stimulating factor (G-CSF) can increase circulating neutrophils by stimulating progenitor cell proliferation and differentiation (Fernandez-Varon and Villamayor, 2007).

In addition to the anticipated myelosuppression following cytotoxic chemotherapy, gastrointestinal toxicity is another common sequela and presents as nausea/vomiting and diarrhea. Gastrointestinal toxicity in dogs and cats is often not as predictable as it is in humans given cytotoxic chemotherapy, and in many cases this is self-limiting and can be managed with general supportive care. In particularly sensitive dogs and cats GI toxicity may be severe and may require intervention such as antiemetics and/or antimicrobials or result in dose reduction. Metronidazole and tylosin are common choices of drugs for chemotherapy-induced diarrhea; however, if gastrointestinal symptoms accompany a febrile neutropenia then antibiotic choice will need to consider bacteria likely to result in sepsis.

Unique toxicities specific to some drugs are discussed in the sections on each drug. Several of the commonly used cytotoxic agents can cause phlebitis and have the potential to create necrosis and tissue sloughing if extravasation occurs. Thus, it is critical that venipuncture and catheter placement are done appropriately and sedation or treatment delay may be necessary if this cannot be performed. Extravasation injury may occur up to 2–4 weeks following treatment and can continue for up to 4 months. Treatment will depend on the agent used; doxorubicin which causes the most severe extravasation injury should be treated by aspiration of any fluid present through the catheter or needle followed by ice-pack treatment three to four times per day. Extravasation of vinca alkaloids should also be addressed by aspiration of any liquid still present in the local area followed by heat therapy three to four times per day. In cases of doxorubicin and vinca alkaloid extravasation, intravenous dexrazoxane or local hyaluronidase administration, respectively, may reduce the subcutaneous toxicity (Schulmeister, 2008). Specific treatment guidelines for common chemotherapy induced toxicities encountered in veterinary oncology have been reviewed in more detail by others (Vail, 2009; Gustafson and Page, 2013).

Hair loss is not a common side effect across all breeds of dogs or cats following chemotherapy but alopecia may be anticipated in breeds of dogs with continuously growing haircoats such as poodles and mixed-breed dogs of poodle lineage, as well as some terriers and Old English Sheepdogs. Cats may lose whiskers following chemotherapy. Regrowth may begin within 1 to 2 months following therapy; however, pet owners should be informed that hair regrowth may occur with slightly different color or texture than the original hair. Communication with pet owners regarding potential side effects prior to selection of a chemotherapeutic protocol is of utmost importance in reducing the distress that is experienced when a pet develops toxicity.

In addition to toxicity experienced by the pet, exposure of the therapist should be considered when administering chemotherapy. Special consideration must be given for proper storage, preparation, administration, and disposal of cytotoxic drugs. The preparation of these drugs should be performed under strict guidelines that involve the use of appropriate personal protective equipment including gloves, masks, and chemical fume hoods. Specific guidelines for cytotoxic drugs are available from the Occupational Safety and Health Administration (OSHA). The potential for exposure of pet owners to chemotherapy residues following treatment generally involve exposure to urine or feces and variable levels of drug may be present in urine depending upon the particular drug and time since administration (Knobloch et al., 2010). Owners should be informed of the potential risk and importance of careful avoidance, collection, and disposal of urine and feces. Young children, pregnant women, and immunocompromised individuals should be instructed to avoid pet wastes for a defined period of time following chemotherapy administration.

Specific Chemotherapeutic Drugs

Alkylating Agents

The alkylating agents were the earliest nonhormonal drugs utilized in the treatment of cancer and comprise a chemically diverse group of compounds. The mechanism of action of the alkylating agents is to interfere with the accessibility of DNA base pairs during replication through the covalent bonding of alkyl groups (e.g., $-CH_2Cl$) to electron-rich nucleophilic groups such as phosphate or hydroxyl moieties. Although a large number of cellular macromolecules contain nucleophilic groups, which are potential sites of alkylation, it is the alkylation of DNA bases that is the major cause of cell death following treatment with alkylating agents. The N-7 and O'6 position of guanine are often a site of alkylation and the net effect can be the loss of guanine from the DNA strand with a resultant strand break. Because their action in causing DNA strand breaks resembles that of radiation, the alkylating agents are frequently referred to as radiomimetics. These drugs can contain one or two reactive groups and are classified as mono- and bifunctional, respectively. The bifunctional alkylating agents are capable of producing inter- or intrastrand DNA cross-links as their major mechanism of cytotoxicity. As a group, these drugs have limited cell cycle specificity and sensitivity of cells is relative to the area under the concentration time curve. In general, the alkylating agents are most useful in tumors of lymphoreticular origin and are less commonly used in sarcomas or carcinomas. Resistance commonly develops after prolonged use and can be drug-specific or across the alkylating class as a whole. Detoxification of these drugs by conjugation with nucleophilic glutathione prevents these drugs from interacting with DNA and increased levels of glutathione or elevated GST can be expected to result in resistance to all drugs within this class. Similarly, increased repair of DNA damage, as is seen with elevated levels of MGMT, can reduce sensitivity of cancer cells to all alkylating agents. Alternatively, resistance that is produced through reduced drug penetration into the cell can be drug specific; for example,

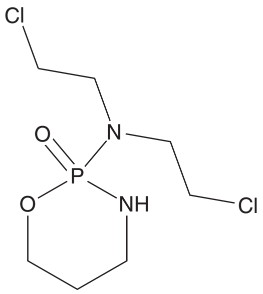

Figure 44.2 Chemical structure of cyclophosphamide, a nitrogen mustard alkylating agent.

melphalan is taken into the cell by the leucine transport system (Del Amo et al., 2008) whereas mechlorethamine is taken in by the choline transporter (Fry and Jackson, 1986) and altered transport affecting one of these drugs does not necessarily cause a reduced efficacy of the other.

Nitrogen Mustards

Cyclophosphamide

The most widely used nitrogen mustard in veterinary medicine is cyclophosphamide (Cytoxan, CTX) (Figure 44.2). Cyclophosphamide is a prodrug that must be converted by the hepatic mixed function oxidase system (cytochrome P450) to an intermediate compound, 4-hydroxycyclophosphamide, which then undergoes spontaneous degradation to the active compound phosphoramide mustard (Cohen and Jao, 1970). Because of the requirement of cytochrome P450 enzymes in the activation of cyclophosphamide, consideration must be given to potential drug–drug interactions in animals coadminstered either inhibitors or activators of these enzymes. The major dose-limiting toxicities in dogs and cats are myelosuppression and neutropenia with thrombocytopenia to a lesser degree. GI toxicity can also be of concern but is more commonly encountered in cats (Fetting et al., 1982). Cyclophosphamide, along with the other nitrogen mustards, is capable of producing alopecia in susceptible animals and causing loss of whiskers in cats. Sterile hemorrhagic cystitis is a potential toxicity that is encountered relatively infrequently and is more likely to develop in dogs than in cats. A metabolite of cyclophosphamide, acrolein, is thought to be responsible for irritation to the bladder following CTX administration. Intravenous administration of furosemide concurrently with cyclophosphamide has been shown to reduce the incidence of sterile hemorrhagic cystitis in dogs (Charney et al., 2003), and when given orally by owners it should be administered in the morning, water intake should be high, and the animal should be given ample opportunity to urinate throughout the day. Administration of MESNA (2-mercaptoethanesulfonate) has also been used prophylactically to bind and detoxify the urotoxic metabolites of cyclophosphamide and ifosfamide (West, 1997). If cystitis occurs with administration of cyclophosphamide the drug should be discontinued and another alkylating agent used in its place (such as chlorambucil). Although maximum plasma concentrations and overall exposure (AUC) to the parent molecule (CTX) are significantly lower when administered by the oral versus IV route, exposure to the active phosphoramide mustard is equivalent between the two routes in dogs (Warry et al., 2011). Thus, doses for oral and IV administration are the same.

Clinical use: Cyclophosphamide is commonly used as part of multiagent protocols in the treatment of canine and feline lymphomas and as part of combination immunosuppressive therapy. Cyclophosphamide may also have utility in the treatment of canine malignant mammary gland tumors (Sorenmo, 2003). Dosing of cyclophosphamide in dogs ranges from 250 mg/m^2 IV or oral bolus, to a more fractionated schedule of 50 mg/m^2 daily for 3 days on a 3-week cycle (Lori et al., 2010). Low-dose cyclophosphamide (10–15 mg/m^2/day) has also been investigated in solid tumors of dogs as part of a metronomic therapy protocol and has demonstrated some efficacy in that setting (Elmslie et al., 2008; Burton et al., 2011). Cyclophosphamide is available as 25- and 50-mg tablets and as a 25-mg/ml injection. Tablets should not be broken or split prior to administration.

Ifosfamide

Ifosfamide (isophosphamide) (Figure 44.3) is a structural isomer of cyclophosphamide that, like cyclophosphamide, requires metabolic activation by hepatic P450 enzymes to form the bifunctional alkylating compound isofosforamide mustard (Creaven et al., 1974). The structural differences between cyclophosphamide and ifosfamide result in a reduced rate of the initial metabolism of ifosfamide to the active form. In addition, a secondary pathway of metabolism that generates chloroacetaldehyde results in the requirement of larger doses of ifosfamide when compared to cyclophosphamide (Wagner, 1994). Although ifosfamide is mostly indicated for treatment of sarcomas in animals, it has a relatively broad

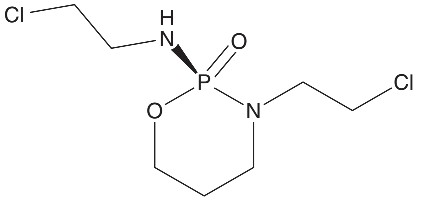

Figure 44.3 The nitrogen mustard alkylating agent ifosfamide, a structural isomer of cyclophosphamide.

range of antitumor activity and has been evaluated in both canine and feline neoplasms. In dogs, a dose of 350 to 375 mg/m^2 has been evaluated in a variety of tumor types with DLT of neutropenia occurring 7 days post treatment (Rassnick et al., 2000). In cats, the recommended starting dose of ifosfamide is 900 mg/m^2 and has been evaluated in the treatment of vaccine-associated sarcoma with an overall response rate of 41% (Rassnick et al., 2006). The dose-limiting toxicity in cats is also neutropenia and the majority of cats tolerate ifosfamide treatment. Nephrotoxicosis is a potential adverse effect in cats treated with ifosfamide. Prophylactic therapy with saline diuresis and MESNA appear to be effective means to prevent sterile hemorrhagic cystitis following ifosfamide treatment and diuresis should be considered to reduce the risk of nephrotoxicosis in cats. The reason for the difference in the dose tolerated by dogs and cats has not been systematically evaluated but is likely to involve species differences in metabolism with regard to exposure to active and/or toxic metabolites. There is evidence of autoinduction of ifosfamide metabolism in humans with multiple fractionated doses resulting in increased levels of metabolites, which may result in increased toxicity (Kurowski et al., 1991; Kaijser et al., 1994), but this has not been evaluated in veterinary patients. As with most cytotoxic drugs, ifosfamide is most likely to provide the greatest benefit when used as part of a combination protocol. Ifosfamide is available in 1 or 3-gram vials for reconstitution and intravenous administration

Mechlorethamine

Mechlorethamine (mustargen), sometimes referred to as “nitrogen mustard,” was the first alkylating agent used clinically (Figure 44.4). Mechlorethamine is a bifunctional alkylating agent that is capable of forming interstrand DNA cross-links as a mechanism of cytotoxicity (Kohn et al., 1966). Unlike cyclophosphamide and ifosfamide, mechlorethamine undergoes spontaneous hydrolysis to form active nucleophilic compounds. Thus, interactions with drugs that inhibit or induce hepatic metabolism are not anticipated with mechlorethamine. Entry of mechlorethamine into cells appears to involve a carrier-mediated, active process and resistant cells demonstrate reduced entry of drug into the cell (Goldenberg et al., 1970). Structural analogs of mechlorethamine, such as cyclophosphamide, melphalan, and chlorambucil, do not appear to inhibit cellular uptake of mechlorethamine. In veterinary medicine, mechlorethamine is most commonly used in the treatment of relapsed or resistant multicentric canine lymphoma as part of the MOPP (mustargen, vincristine, procarbazine, prednisone) protocol (Rassnick et al., 2002; Brodsky et al., 2009; Northrup et al., 2009). Myelosuppression and gastrointestinal toxicity are the dose-limiting toxicities reported for mechlorethamine in combination protocols. The most commonly reported dose for mechlorethamine in dogs when used in combination protocols in 3 mg/m^2 on days 0 and 7 of a 21-day cycle. Mechlorethamine is available as a lyophilized powder in 10-mg vials.

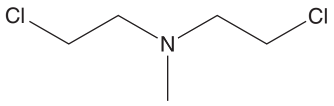

Figure 44.4 Mechlorethamine, or mustargen, sometimes referred to as “nitrogen mustard” was the first alkylating agent to be used clinically.

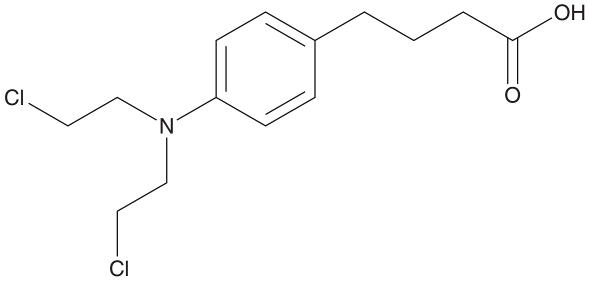

Figure 44.5 Chlorambucil, an orally bioavailable nitrogen mustard alkylating agent.

Chlorambucil

Chlorambucil (leukeran) (Figure 44.5) is an orally bioavailable alkylating agent that, along with the metabolite phenylacetic acid mustard, has direct bifunctional alkylating ability (Mitoma et al., 1977; Goodman et al., 1982). Chlorambucil is most often used in slower growing neoplasia such as chronic lymphocytic leukemia (CLL) but has been used in other types of cancers such as lymphoma and mast cell tumor (Taylor et al., 2009; Campbell et al., 2013). In cats, chlorambucil has been used in the treatment of GI lymphoma in combination with glucocorticoids, where it demonstrated favorable efficacy and was well tolerated (Stein et al., 2010). Metronomic therapy with chlorambucil has also been reported for a variety of neoplasms in dogs and may be a treatment option for dogs with transitional cell carcinoma of the urinary bladder (Leach et al., 2012; Schrempp et al., 2013). Chlorambucil has also been utilized as an alternative to cyclophosphamide when the latter has resulted in the development of sterile hemorrhagic cystitis. Chronic oral dosing in dogs with CLL generally begins with 3 to 6 mg/m^2 daily for 1 to 2 weeks followed by a reduction to 3 to 6 mg/m^2 every other day. Metronomic dosing studies have used a daily dose of 4 mg/m^2 in dogs while a bolus dosing regimen of 20 mg/m^2 every 2 weeks has been evaluated and found to be well tolerated in cats with GI lymphoma. The major dose-limiting toxicity for

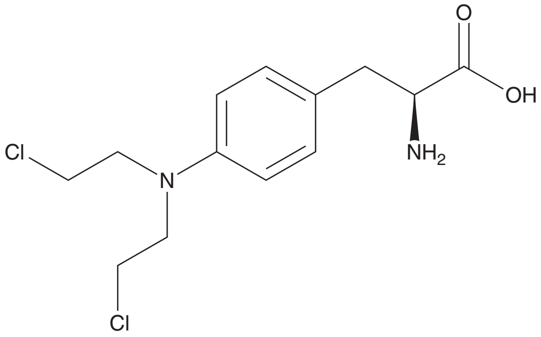

Figure 44.6 Melphalan, structurally similar to chlorambucil, is charged and hydrophilic and requires active uptake into cells by amino acid transporters.

chlorambucil is myelosuppression with neutropenia and a lesser degree of thrombocytopenia. In humans, myoclonus has been reported as a rare side effect following both high- and low-dose treatment and myoclonus following chlorambucil treatment has also been reported in a cat (Benitah et al., 2003). Chlorambucil is available as 2-mg tablets for oral administration. Tablets should not be broken and animal doses should be adjusted to the nearest whole tablet.

Melphalan

Melphalan (alkeran) is a nitrogen mustard-containing alkylating agent (L-phenylalanine mustard) that has direct DNA alkylating properties (Figure 44.6). Structurally, melphalan is similar to chlorambucil yet it is charged and hydrophilic at neutral pH and thus requires active uptake by amino acid transporters, which can be blocked by the amino acid leucine (Del Amo et al., 2008). Melphalan is orally bioavailable with a relatively large percentage eliminated unchanged in the urine in humans (Tew et al., 2001). Melphalan is most commonly used for the treatment of multiple myeloma in dogs and cats where initial positive responses are frequent, although complete eradication of all neoplastic myeloma cells is unlikely and eventual relapse is anticipated (Matus et al., 1986). Melphalan has also been used as a rescue therapy for relapsed lymphoma in dogs (Alvarez et al., 2006; Back et al., 2013). Myelosuppression and, in particular, a delayed thrombocytopenia is the major dose-limiting toxicity for melphalan and monitoring of complete blood count (CBC), including platelet counts, should be performed every 2 weeks for the first 2 months of therapy, then monthly thereafter. Melphalan therapy appears to be more myelosuppressive in cats than in dogs (Hanna, 2005). Initial dosing of melphalan is 0.1–0.2 mg/kg by mouth daily for 7–10 days followed by a reduction to 0.05 mg/kg daily, continuously. Alternatively, a pulse-dosing regimen of 7 mg/m^2 by mouth, daily for 5 days every 3 weeks has been utilized and is well-tolerated by dogs. In cats, long-term therapy consists of 0.1 mg/kg by mouth once every 7 days, continuously (Vail, 2013). Melphalan is available for oral use as 2-mg tablets and for intravenous injection as a 50-mg vial.

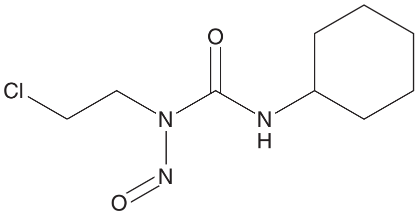

Figure 44.7 Structure of the lomustine, or CCNU, belonging to the nitrosurea class of alkylating agents.

Nitrosoureas

Cyclohexylchloroethylnitrosourea (lomustine)

Cyclohexylchloroethylnitrosurea (CCNU) is a monofunctional alkylating agent with a single chloroethyl group (Figure 44.7) that is capable of producing DNA–DNA and DNA–protein crosslinks as a mechanism of cytotoxicity (Kohn, 1977). CCNU is extremely lipophilic and capable of crossing the blood–brain barrier and thus has been used to treat neoplasia of the central nervous system. The main indications for use of CCNU in veterinary medicine are in brain tumors, histiocytic sarcoma, mast cell tumors, and epitheliotropic, and relapsed or refractory lymphomas (Fulton and Steinberg, 1990; Moore et al., 1999; Rassnick et al., 1999; Williams et al., 2006; Skorupski et al., 2007; Saba et al., 2009). CCNU is extensively metabolized in the liver with a large "first pass" effect resulting in undetectable plasma levels of the parent compound and rapid appearance of the active monohydroxylated metabolites (Lee et al., 1985). In both cats and dogs, CCNU has delayed and cumulative effects on the bone marrow causing neutropenia and thrombocytopenia with a nadir that can range from 7 to 28 days, and often has a prolonged recovery period (Moore et al., 1999; Rassnick et al., 2001). The extensive hepatic metabolism that occurs may also be partly responsible for the development of hepatotoxicity with chronic use, requiring dose reduction or complete cessation of lomustine therapy (Henry et al., 1973; Heading et al., 2011). Increases in hepatic enzymes occur in almost 90% of dogs receiving CCNU but the frequency and severity of hepatic enzyme elevation may be reduced by the concurrent administration of denamarin, a drug containing *S*-adenosylmethionine and sylibinin, which have both been evaluated for various types of hepatopathy in dogs (Skorupski et al., 2011). The most common dosing regimens for CCNU are 70–80 mg/m^2 PO every 3 weeks in dogs and 50–60 mg/m^2 PO every 4–6 weeks in cats. Lomustine is available as 10, 40, and 100-mg capsules.

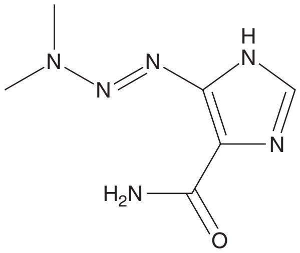

Figure 44.8 Dacarbazine, an imidazole-carboxamide derivative alkylating agent.

Other Alkylating Agents

Dacarbazine

Dacarbazine (DTIC) is an imidazole–carboxamide derivative that is structurally related to purines (Figure 44.8) and its development was initially an attempt to generate an antimetabolite that would inhibit purine synthesis. However, the principle mechanism of action of this drug is to induce methyl adducts to DNA and the formation of O-6 methylguanine is the main lesion responsible for the cytotoxicity (and mutagenic) effect of DTIC (Marchesi et al., 2007). DTIC is a non cell cycle-specific drug that is active in all phases of the cell cycle. Like cyclophosphamide and ifosfamide, dacarbazine requires metabolic activation by hepatic cytochrome P450 enzymes to form the active species 5-[3-methyl-triazen-1-yl]-imidazole-4-carboxamide (MTIC) and the relative activity as an effective anticancer drug may depend upon the level of P450 activity (Reid et al., 1999). Coadministration of drugs that alter P450 activity can thus be anticipated to result in important drug–drug interactions that can reduce activity or enhance toxicity of dacarbazine. Administration to cats has not been evaluated in terms of their ability to convert the parent drug to the active metabolite, and thus use in cats is not recommended. The main dose-limiting toxicity of DTIC is gastrointestinal and generally presents as vomiting and diarrhea. In addition, a delayed myelosuppression may occur at 2 to 3 weeks postadministration and can be severe in some cases. Thrombocytopenia may also be encountered 1 to 2 weeks following therapy and may result in treatment delays (Griessmayr et al., 2009). Dacarbazine has poor oral bioavailability and is given by the intravenous route, and renal tubular secretion appears to be the major elimination route; dose adjustments are recommended for patients with renal or hepatic disease. DTIC does not cross the blood–brain barrier effectively and thus is not used for intracranial tumors. In veterinary medicine DTIC has mainly been used in the treatment of relapsed or resistant canine lymphoma (Van Vechten et al., 1990; Flory et al., 2008; Griessmayr et al., 2009) and in advanced-stage hemangiosarcoma (Dervisis et al., 2011).

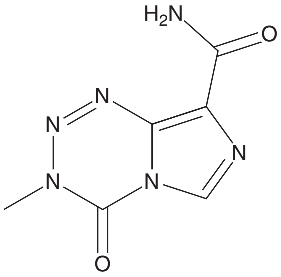

Figure 44.9 Temozolamide is an orally bioavailable alkylating agent related to dacarbazine; it has better blood–brain barrier penetration making it useful for CNS neoplasia.

The dose of dacarbazine ranges from 800–1,000 mg/m^2 every 2–3 weeks as a single agent to 600 mg/m^2 IV when used in combination protocols. Dacarbazine is generally administered as a 4 to 5-hour infusion in 5% dextrose solution or normal saline, as more rapid administration can result in severe phlebitis. Dacarbazine is available as a lyophilized powder in 100 or 200-mg vials.

Temozolomide (temodar)

Temozolomide (Figure 44.9) is an alkylating agent that is related to dacarbazine. It is a prodrug whose active metabolite is the same as dacarbazine (MTIC); however, there are important differences with regard to the mode of activation and pharmacokinetics of temozolomide that make it distinct from dacarbazine in its clinical applications. Temozolomide does not require hepatic activation by P450 enzymes but is spontaneously hydrolyzed at physiological pH to form MTIC (Marchesi et al., 2007). Additionally, temozolomide is orally bioavailable and is capable of crossing the blood–brain barrier as the parent compound, which can then be converted to the active MTIC species within brain tissues making it useful for CNS neoplasia (Marchesi et al., 2007). Temozolomide has been evaluated in clinical trials of canine cancer and was compared to dacarbazine for relapsed or refractory lymphoma, where the responses were similar in terms of rate and duration but temozolomide caused less hematological toxicity and was more convenient to administer (Dervisis et al., 2007). The dose of temozolomide evaluated in this study ranged from 60 to 100 mg/m^2 PO daily for 5 days on a 3-week cycle. Temozolomide is available as 5, 20, 100, 140, 180, and 250-mg capsules.

Procarbazine

Procarbazine (PCB) (Figure 44.10) is another prodrug alkylating agent that does not have cytotoxic effects in cells without chemical or metabolic activation (Gale et al., 1967). Additionally, the exact mechanism of cytotoxicity by procarbazine is not fully understood; however, evidence exists that sensitivity to procarbazine is associated with reduced cellular levels of the enzyme

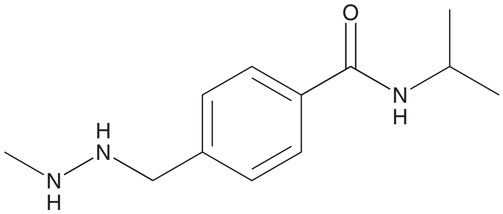

Figure 44.10 Procarbazine

responsible for repair of O-6 methylguanine adducts, inferring methylation of guanine as a mechanism of action (Schold et al., 1989). Procarbazine is rapidly and completely absorbed after oral dosing and the metabolites appear rapidly in plasma following oral dosing. Procarbazine appears to cross the blood–brain barrier in dogs and there is evidence for autoinduction of metabolism of procarbazine with metabolite levels increasing after multiple daily doses, which correlate with increased antitumor activity experimentally (Oliverio et al., 1964; Shiba and Weinkam, 1982, 1983). Procarbazine is also an inhibitor of monoamine oxidase (MAO) and drug–drug interactions may be expected with coadministration of sympathomimetics, tricyclic antidepressants, or phenothiazines, as well as with drugs that inhibit hepatic P450 enzymes such as cimetidine (Friedman et al., 2001). Procarbazine is generally used as part of combination therapy protocols for relapsed lymphoma in dogs (Rassnick et al., 2002, 2010; Brodsky et al., 2009; Northrup et al., 2009). The recommended dose is 50 mg/m^2 PO daily for 14 days of a 28-day cycle, although alternate-day dosing may be required due to limitations of tablet size for some dogs. Procarbazine is available in 50-mg capsules for oral administration.

Antitumor Antibiotics

Doxorubicin (Adriamycin)

Doxorubicin (Figure 44.11) is an anthracycline antibiotic that that was first isolated from *Streptomyces peucetius* var. *caesius* (Arcamone et al., 1969). Doxorubicin exhibits pleiotropic antitumor activity with evidence for cytotoxicity from direct distortion of the DNA double-helix through intercalation (Neidle, 1979), free radical formation through redox activity and reduction to the semiquinone (Davies and Doroshow, 1986), inhibition of DNA and RNA polymerases (Zunino et al., 1975), inhibition of the activity of DNA topoisomerase II (Tewey et al., 1984), alteration in intracellular calcium homeostasis (Oakes et al., 1990), lipid peroxidation and alterations in cell membrane functions (Tritton, 1991), and inhibition of thioredoxin reductase resulting in reduced activity of ribonucleotide reductase (Mau and Powis, 1992). While each of the putative actions have been implicated in the efficacy and toxicity of doxorubicin, with the relative contribution of each still under debate, it is known that the majority of doxorubicin is found within the nucleus and intercalated into the DNA double helix. In addition, there does appear to be some degree of base recognition and sequence specificity to the intercalation of doxorubicin (Trist and Phillips, 1989). The cellular pharmacology of doxorubicin is characterized by extensive intracellular accumulation where it binds to DNA, associates with membranes, and is stored in various cellular compartments. Classically, doxorubicin has been classified as a topoisomerase II inhibitor and the reduced sensitivity seen in cells that have down-regulated topoisomerase II underscores the relative importance of that interaction for antitumor activity. The topoisomerase enzymes are ubiquitous nuclear enzymes that are responsible for relaxing supercoiled double-stranded DNA to allow for DNA replication and RNA transcription. The torsional strain on DNA is relieved by formation of a single-stranded nick (topoisomerase I) or a double-stranded nick (topoisomerase II) followed by passage of DNA through the nick and religation. The topoisomerase inhibitors bind to and stabilize the DNA/topoisomerase complex which prevents religation and ultimately leads to lethal double strand breaks. As discussed in Section Tumor Cell Sensitivity, resistance to doxorubicin may also be due to the classic MDR phenotype resulting from up-regulation of MDR1 and other ABC transporters.

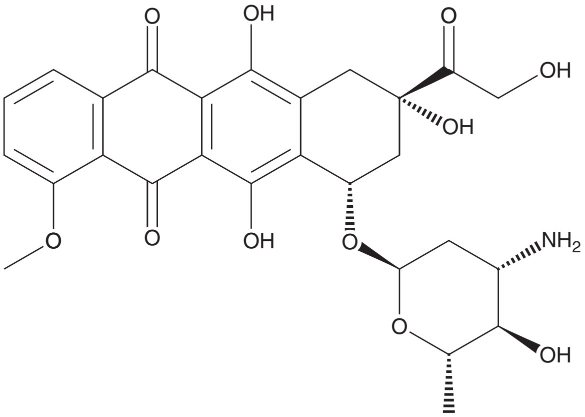

Figure 44.11 Structure of the antitumor antibiotic doxorubicin (Adriamycin). Doxorubicin in one of the most commonly used chemotherapeutic agents in veterinary oncology.

Doxorubicin is poorly bioavailable and is administered by the intravenous route. Following intravenous administration in dogs, doxorubicin concentrations drop rapidly in plasma as the drug distributes extensively to tissues, with the extent of distribution to specific tissues suggested to be determined by tissue DNA content (Terasaki et al., 1982). In dogs, a three-compartment model was shown to fit doxorubicin kinetics with half-lives of the α, β, and γ phases of 0.04, 0.44, and 19.8 hours, respectively

(Gustafson et al., 2002). Clearance in dogs is reported to be 46.5 l/h and steady-state volume of distribution is approximately 500 liters (Gustafson et al., 2002). In both humans and dogs, however, there is substantial interpatient variability in the pharmacokinetics of doxorubicin, leading to variability in toxic effects such that dose reductions are not uncommon following the first treatment. Elimination of doxorubicin occurs through renal and biliary excretion of parent drug and through metabolism to doxorubicinol, via aldo-keto reductases, and 7-hydroxy aglycone, via reductive cleavage in both hepatic and extrahepatic tissues (Ahmed et al., 1981).

The dose-limiting toxicities for doxorubicin include myelosuppression, gastrointestinal toxicity, and a well-established cumulative cardiotoxicity that places a limit the lifetime exposure in patients. For dogs, this lifetime limit is often set at 150 mg/m^2, which provides approximately five treatment cycles. This limit may be increased as dictated by a need for additional therapy such as with relapsed lymphoma after careful cardiac evaluation. Formation of free radicals and iron accumulation in cardiac mitochondria appear to underlie the development of congestive heart failure, and cardiac function should be carefully evaluated prior to initiation of therapy as well as prior to each treatment, particularly in at-risk breeds such as Boxers and Doberman Pinschers. During the course of treatment, any changes in cardiac function, such as the development of new murmurs, arrhythmias, or pulse deficits, should be pursued with a full diagnostic evaluation.

The administration of the iron-chelating agent dexrazoxane (Zinecard) has been shown in human patients to reduce the risk for cardiotoxicity and is increasingly used for this purpose in veterinary medicine Dexrazoxane has also been used to reduce the local tissue damage from extravasation of doxorubicin during administration. Doxorubicin causes some of the most severe local tissue necrosis following extravasation and this can result in a requirement for surgical debridement or amputation. Thus, it is critical that a carefully placed catheter be used for doxorubicin administration. Sedation may be required in some patients to ensure that a catheter is placed appropriately. If the catheter is not placed on the first stick, another vein should be chosen for use and treatment delays may be required to ensure that catheter placement is adequate. Cats administered doxorubicin often may not display the overt signs of cardiac toxicity that are seen in dogs but may develop renal tubular damage following repeated dosing, and monitoring of serum creatinine and urine specific gravity are recommended during therapy (O'Keefe et al., 1993). Doxorubicin produces poikilocytosis in cats (O'Keefe and Schaeffer, 1992). Doxorubicin can also cause acute anaphylactic reactions during administration due to histamine release; this often results in stopping the infusion and treatment with antihistamines and/or corticosteroids. In some situations a clinician may choose not to continue administration while some will continue but at a slower infusion rate. Slower rates of infusion are associated with reduced incidence of acute cardiac toxicity that can be seen with bolus dosing.

Standard dosing of doxorubicin in dogs is 30 mg/m^2, diluted in 50–100 ml of saline and given intravenously over 20–30 minutes every 3 weeks, with the slower infusions resulting in less risk for acute adverse reactions. In dogs that are less than 15 kg and in all cats, the dose is 1 mg/kg intravenously every 3 weeks. This difference in dosing is due to the fact that using the body surface area prescription base in small dogs and cats seems to lead to a relative overdose and increased toxicity. Doxorubicin has a very broad spectrum of antitumor activity and is used as a single agent and as part of many combination protocols for canine and feline lymphoma, osteosarcoma, and most neoplasms of mesenchymal (sarcoma) and epithelial (carcinoma) origin. Doxorubicin is available as a 2 mg/ml injectable solution. Other formulations of doxorubicin are available such as a pegylated, liposome-encapsulated form (Doxil) that has been demonstrated to be less cardiotoxic (Working et al., 1999) and has been evaluated in a few canine trials (Vail et al., 1997; Sorenmo et al., 2007; Teske et al., 2011).

Mitoxantrone

Mitoxantrone is an anthracenedione drug (Figure 44.12) that was developed in an effort to find a less toxic alternative to the structurally related anthracyclines (DOX). Mitoxantrone maintains a similar spectrum of cytotoxic mechanisms to doxorubicin, including DNA intercalation, inhibition of DNA and RNA polymerases, and inhibition of topoisomerase II (Foye et al., 1982; Crespi et al., 1986). However, mitoxantrone does not possess the same ability to induce cardiac dysfunction or produce local tissue necrosis if extravasated. This is due to the reduced ability to undergo one-electron reduction and generate free radicals as well as a lack of lipid peroxidation in cardiac myocytes (Patterson et al., 1983; Nguyen and Gutierrez, 1990). This results in mitoxantrone being used in some cases as a substitute for doxorubicin, although the spectrum of anticancer activity is narrower than that of doxorubicin. Following intravenous administration there is rapid and extensive distribution to tissues with an apparent volume of distribution of 26 l/kg and a long persistence of drug residues in tissues, with approximately 30% of the drug eliminated unchanged in urine and feces (Lu et al., 1984). The dose-limiting toxicities include gastrointestinal disturbance and myelosuppression; cardiac toxicity has not been reported in dogs. Resistance to mitoxantrone can be a result of increased drug efflux from up-regulation of MDR1, MRP, or BCRP as well as

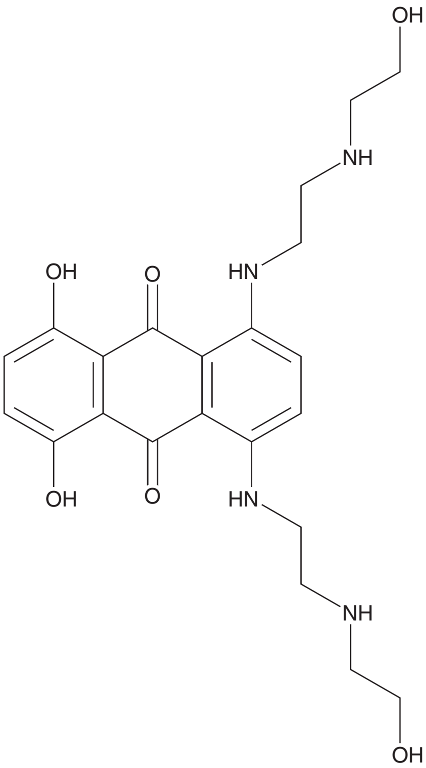

Figure 44.12 Mitoxantrone, an anthracenedione chemotherapy agent, with a similar spectrum of activity to doxorubicin and a lower likelihood of cardiac toxicity.

through alterations in topoisomerase II function (Hazlehurst et al., 1999).

Dosing is generally instituted at 5–6 mg/m^2 every 3 weeks as a slow intravenous bolus, and indications include lymphoproliferative disorders (lymphomas and leukemias) and potentially transitional cell carcinoma of the urinary bladder. Mitoxantrone may be chosen as a maintenance therapy for lymphoma in dogs that have reached their cumulative maximum dose of doxorubicin or in dogs at high risk for cardiotoxicity from doxorubicin. Mitoxantrone is available as a 2 mg/ml injectable formulation.

Actinomycin D

Actinomycin D (Dactinomycin; DACT) (Figure 44.13) is an actinomycin antibiotic produced by various species of *Streptomyces*. DACT interacts with both single and double-stranded DNA in a sequence-specific manner (gaunine–cytidine base pairs) and results in a potent inhibition of transcription and RNA translation, which block protein synthesis (Kawamata and Imanishi, 1960). DACT is not orally bioavailable and is administered intravenously. Following IV dosing in dogs there is a rapid fall in plasma drug concentrations with a concomitant accumulation of drug in peripheral tissues. DACT resides in tissues for an extended period of time with a tissue half-life of 47 hours in the dog (Galbraith and Mellett, 1975). Elimination of DACT is via biliary and urinary routes and there appears to be minimal metabolism (Galbraith and Mellett, 1975). Cross-resistance to anthracyclines and mitoxantrone has been demonstrated, implicating MDR1 up-regulation and drug efflux as a resistance mechanism to DACT.

Dose-limiting toxicities for actinomycin-D are myelosuppression and gastrointestinal disturbances. DACT is also capable of producing tissue necrosis if extravasation occurs during administration and thus care must be taken during placement of catheters. Actinomycin D is a radiation sensitizer by virtue of the inhibition of repair of sublethal radiation-induced DNA damage (D'Angio et al., 1959). DACT administration can also result in a phenomenon known as radiation recall where patients receiving DACT will experience inflammatory reactions in previously irradiated sites. Administration of corticosteroids may lessen these effects.

Actinomycin D is often used as part of combination protocols in the setting of relapsed lymphoma in dogs, or as a doxorubicin substitute in dogs with preexisting cardiac dysfunction. The standard dose is 0.5–0.75 mg/m^2 IV every 3 weeks and is available in 0.5-mg vials.

Antimetabolites

The antimetabolites are drugs that interfere with normal cellular functions, such as synthesis of DNA, by serving as false substrates for normal biochemical processes involved the synthesis of nucleotides or inhibiting further extension of the new DNA strand, leading to the inhibition of cell division. The antimetabolite class of drugs are cell-cycle specific and their toxic effects reflect activities in proliferating cells such as bone marrow and the gastrointestinal tract. These drugs do not directly bind to DNA, and thus are not associated with the late effects of secondary malignancies like the alkylating agents.

Methotrexate

Methotrexate (MTX) (Figures 44.14 and 44.15) is a folate analog that inhibits the synthesis of purine nucleotides. Reduced folate is required in the biosynthesis of purines and the cellular generation of reduced folate is dependent upon the enzyme dihydrofolate reductase (DHFR). Methotrexate competitively binds and inhibits DHFR, preventing the formation of reduced folate; this is the major mechanism of antitumor action of this drug (Bertino, 1963). Intracellular metabolism of methotrexate leads to the addition of glutamic acid residues to the drug (polyglutamation) and these polyglutamates act as direct inhibitors of folate-dependent enzymes that function in purine and thymidylate synthesis (Fabre et al., 1984; Allegra et al., 1985). Methotrexate entry into cells is active and depends on the function of the reduced

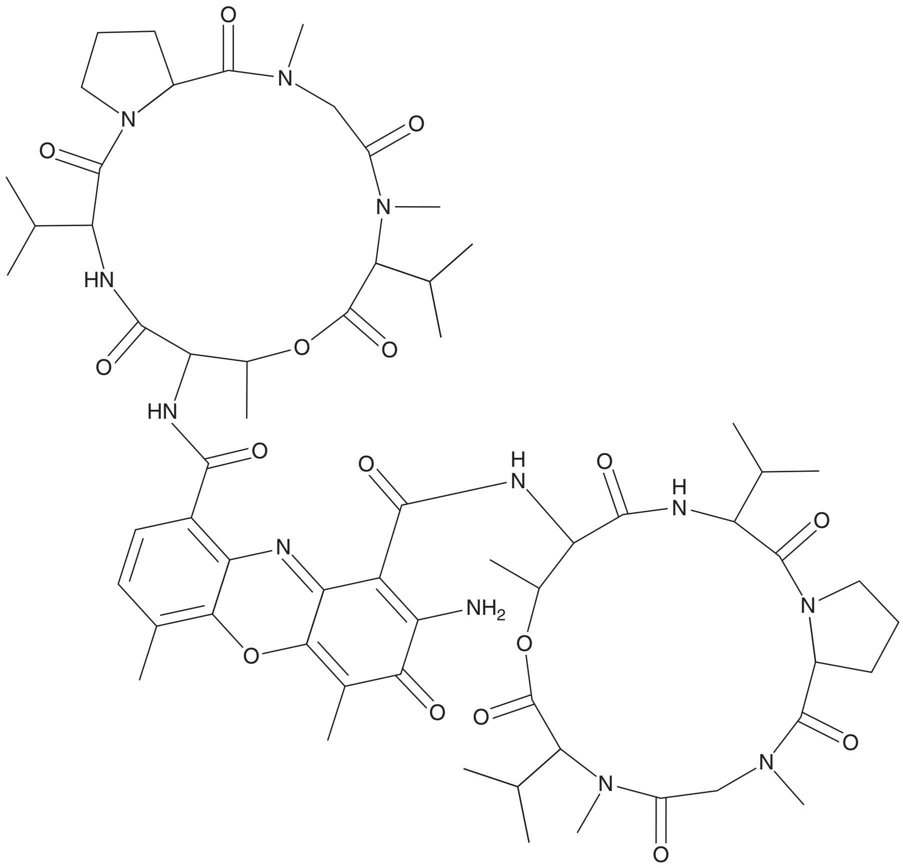

Figure 44.13 Structure of the antitumor antibiotic actinomycin D (dactinomycin).

folate carrier. Oral absorption of methotrexate is almost complete at lower doses but is reduced at high doses, suggesting saturation of absorption processes. MTX also undergoes enterohepatic cycling with some metabolism by intestinal bacteria (Wan et al., 1974). This enterohepatic cycling leads to gastrointestinal toxicity becoming evident at doses that do not produce significant myelosuppression. At higher doses, myelosuppression is also a dose-limiting toxicity with methotrexate. In humans, high-dose regimens are utilized and the myelosuppression is "rescued" by the administration of a source of reduced folate (Leucovorin). This drug has also been used in the prevention of toxicity following accidental ingestion of methotrexate in dogs (Lewis et al., 2010). Methotrexate has found limited use in veterinary medicine as a part of combination protocols for lymphoma. It is available as 2.5-mg tablets for oral administration and as 20, 50, 100, 200, 250-mg and 1-g vials for injection.

Cytosine Arabinoside (Cytarabine)

Cytosine arabinoside (Ara-C) is an analog of the purine nucleotide deoxycytidine, differing only by the presence of a hydroxyl group on the sugar so that it becomes arabinose instead of deoxyribose (Figure 44.16). The main effects of Ara-C in tumor cells are inhibition of DNA polymerase, which impedes DNA replication and repair (Furth and Cohen, 1968), and, more importantly, incorporation into DNA, which is the main mechanism of cytotoxicity for this agent (Kufe et al., 1980). In fact, there

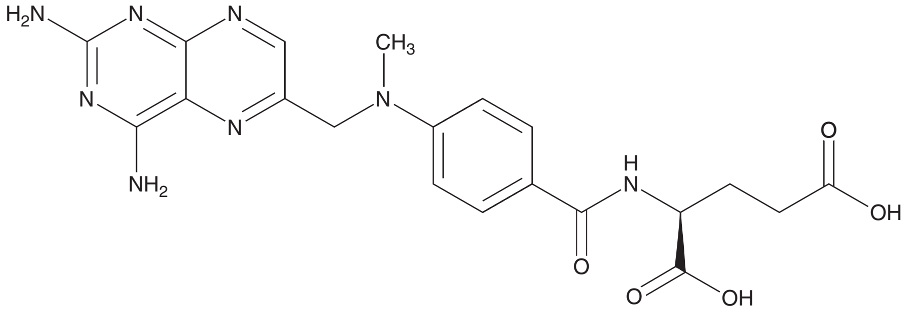

Figure 44.14 Structure of the antimetabolite and folic acid analogue methotrexate.

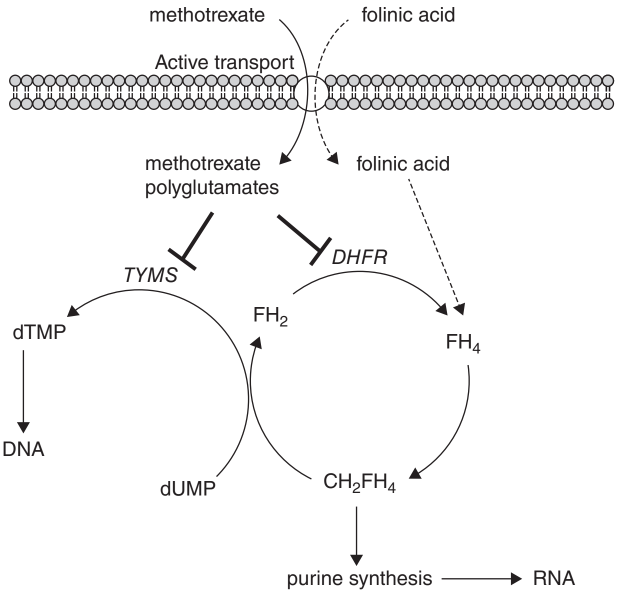

Figure 44.15 Mechanism of action for methotrexate. Methotrexate is actively transported into the cell by the reduced folate carrier. Formation of intracellular methotrexate-polyglutamates results in increased intracellular retention of drug. Methotrexate inhibits the activity of the dihydrofolate reductase enzyme (DHFR), preventing the conversion of dihydrofolate (FH_2) to tetrahydrafolate (FH_4) and blocking the synthesis of purine nucleotides. Methotrexate also functions to block the conversion of deoxyuridine monophosphate (dUMP) to thymidine monophosphate (dTMP), a reaction catalyzed by the enzyme thymidylate synthase (TYMS) and requiring reduced folate. Administration of exogenous sources of reduced folate (such as folinic acid, or Leucovorin) can reverse the cytotoxicity of methotrexate.

is a linear relationship between the amount of Ara-C incorporated into DNA and tumor cell survival (Kufe and Spriggs, 1985). Once Ara-C is incorporated into DNA, tumor cells do not seem to be able to remove it and this inhibits template function and DNA strand elongation. Ara-C is a cell-cycle phase-specific drug with greatest activity against cells in S phase. As a nucleotide analog, Ara-C is actively transported into cells utilizing a shared transporter for physiological nucleotides, and at high concentrations the transport process can become saturated and further entry is via passive diffusion (Jamieson et al., 1990). Once inside the cell, a series of phosphorylation processes convert Ara-C into the active triphosphate form (Ara-CTP) by the activities of deoxycytidine kinase, deoxycytidine monophosphate (dCMP) kinase, and nucleoside diphosphate kinase (Garcia-Carbonero et al., 2001).

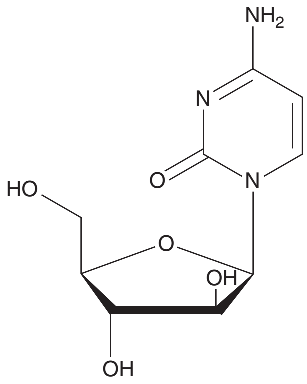

Figure 44.16 Cytosine arabinoside (cytarabine) is an analog of the purine nucleotide deoxycytidine.

Metabolism of Ara-C is primarily through deamination in hepatic and extraheptic tissues. The major dose-limiting toxicities of Ara-C are myelosuppression and, depending upon the dosing regimen used, gastrointestinal disturbances. Ara-C is water soluble and most often dosed by IV bolus, repeated subcutaneous injection, or IV infusion. Ara-C is capable of crossing the blood–brain barrier and is potentially useful in cases of intracranial lymphomas, although the route of administration may affect the overall efficacy as constant-rate infusion (CRI) dosing will maintain steady-state plasma concentrations longer, providing more exposure to the CNS than SQ dosing (Crook et al., 2013). The pharmacokinetics of Ara-C in dogs has been evaluated (Crook et al., 2013) and following SQ dosing, maximum plasma concentrations are achieved within 1 hour and the elimination half-life is 1.35 hours. Following initiation of a CRI, maximum plasma concentrations are achieved after 4 hours, at which point steady-state concentrations are maintained until termination of the CRI. Terminal half-life of Ara-C following CRI is similar to SQ at 1.2 hours. Ara-C is infrequently used in combination chemotherapy for lymphomas and leukemias, unless there is evidence of CNS involvement; however, a small study has demonstrated that there may be some improvement in canine patients with stage V lymphoma when Ara-C is administered in conjunction with the first two cycles of a standard CHOP-based (cyclophosphamide, doxorubicin, vincristine, prednisolone) combination protocol (Marconato et al., 2008a). CRIs of Ara-C over multiple days, as was done in the study above, may require bone marrow support with rhG-CSF and erythropoietin to avoid severe myelosuppression. Ara-C is more commonly used in the treatment of meningoencephalitis of unknown origin, often in combination with prednisolone. Cytosine arabinoside is available for IV or SQ injection in vials of 100 and 500 mg or 1 and 2 grams.

Gemcitabine

Gemcitabine (2′2′-difluorodeoxycytidine) (Figure 44.17) is a cytosine analog that is structurally similar to cytosine arabinoside but has a spectrum of activity that includes a variety of solid tumors. Gemcitabine entry into the cell is dependent upon carrier-mediated transport using nucleoside transporters (Mackey et al., 1998). Like

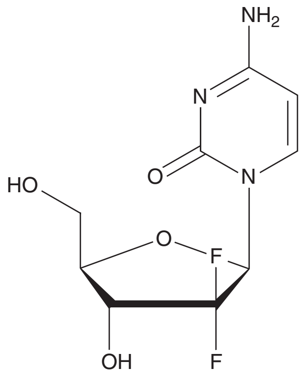

Figure 44.17 Chemical structure of gemcitabine.

Ara-C, gemcitabine must be metabolized inside the cell to the triphosphate derivative (dFdCTP), which then gets incorporated in DNA causing termination of strand elongation. Although gemcitabine is not as effective at termination of chain elongation as cytosine arabinoside, the long intracellular half-life of the triphosphate (up to 72 hours) provides a favorable pharmacokinetic profile with regard to tumor cell exposure (Plunkett et al., 1995). Additionally, the intermediate metabolites of gemcitabine have activities that enhance the overall growth inhibitory properties of the drug, such as inhibition of ribonucleotide reductase and stimulation of the enzyme responsible for activation (deoxycytidine kinase); thus gemcitabine appears unique in its “self-potentiation” capabilities (Plunkett et al., 1995).

Gemcitabine is administered by the intravenous route as it has low oral bioavailability, likely due to a high first-pass effect with hepatic conversion to the deaminated metabolite (dFdU), which also has some cytotoxic effects (Veltkamp et al., 2008). Gemcitabine is given as a slow infusion because this route leads to higher intracellular concentrations than bolus dosing. The pharmacokinetics of gemcitabine in dogs has been evaluated following infusion and bolus dosing and results demonstrate linear pharmacokinetics for the parent compound (Freise and Martin-Jimenez, 2006a, 2006b). After intravenous infusion, the maximum plasma concentration (C_{max}) occurred at 2 hours and gemcitabine clearance, steady-state volume of distribution, and half-life were 0.4 l/h*kg, 0.8 l/kg, and 1.5 hours, respectively (Freise and Martin-Jimenez, 2006b). Gemcitabine has been evaluated in a number of tumor types including osteosarcoma and a variety of carcinomas, often being combined with carboplatin (Marconato et al., 2008b, 2011; Dominguez et al., 2009; Elpiner et al., 2011; McMahon et al., 2011; De Brito Galvao et al., 2012). Gemcitabine has also been evaluated in cats in combination with carboplatin (Martinez-Ruzafa et al., 2009) or as a radiosensitizing agent (Jones et al., 2003). Doses of gemcitabine vary with the treatment protocol and the other agents used in conjunction; reported doses include 350–400 mg/m^2 weekly for 5 weeks; 800 mg/m^2 given over 60 minutes every 7 days; 625 mg/m^2 biweekly; and 2 mg/kg on days 1 and 8 of a 21-day cycle. In all cases, neutropenia appears to be the dose-limiting toxicity with gastrointestinal toxicity generally mild and self-limiting. The lack of clear benefit to gemcitabine therapy for any specific tumor type to date may suggest that further studies into the proper scheduling and dosing of this agent are required in veterinary medicine. Gemcitabine is available in 200 and 1000-mg vials of lyophilized powder.

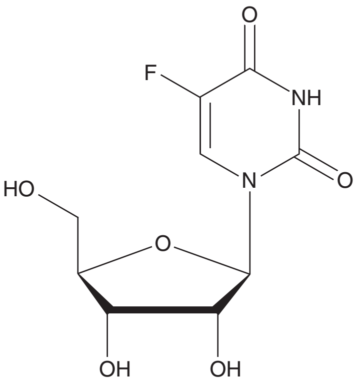

Figure 44.18 5-fluorouracil is a halogenated analog of uracil.

5-fluorouracil

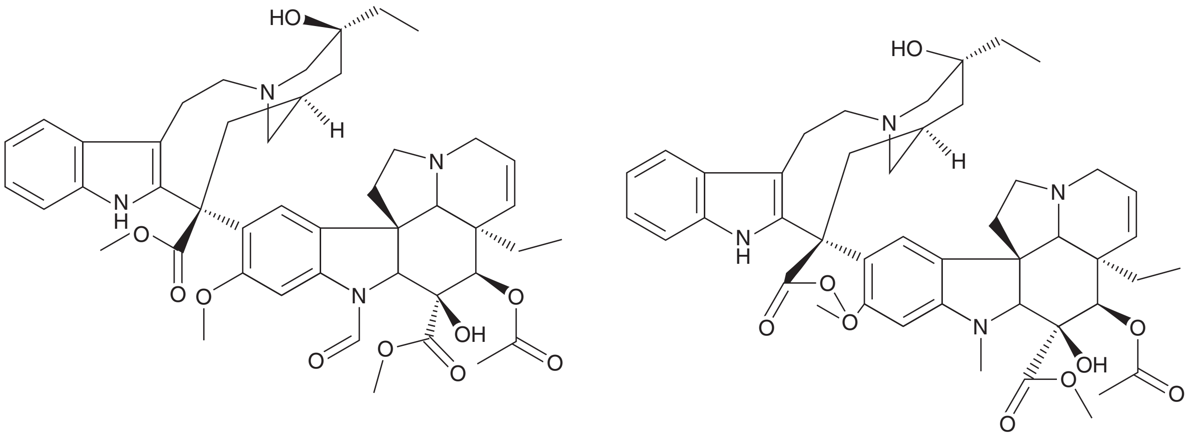
5-fluorouracil (5-FU) (Figure 44.18) is a halogenated analog of uracil that was the result of early attempts to design “targeted” agents in cancer therapy when it was noted that tumor cells utilize uracil more avidly than normal cells, providing a rational means by which neoplastic cells might be targeted (Rutman et al., 1954). 5-FU is actively transported into cells by a shared system that also transports uracil, adenine, and hypoxanthine (Wohlhueter et al., 1980). Similar to Ara-C and gemcitabine, 5-FU is converted enzymatically to active nucleotide forms intracellularly. The mechanisms by which 5-FU results in cytotoxicity include interference with RNA synthesis and function, inhibition of thymidylate synthetase leading to depletion of thymidine mono- and triphosphates, and incorporation into DNA reducing stability (Grem, 2001). In human oncology, 5-FU has found use in a number of solid tumor types including carcinomas of the colon and breast, and is often used in combination with other drugs or ionizing radiation. 5-FU is administered by the intravenous route and undergoes extensive hepatic and extrahepatic metabolism, primarily by the enzyme dihydropyrimidine dehydrogenase (DPD) (Kuan et al., 1998). In dogs, myelosuppression and gastrointestinal toxicity are commonly encountered. In both dogs and cats 5-FU causes neurotoxicity and, in cats, this is severe enough that use of the drug is contraindicated for the species (Harvey et al., 1977; Dorman et al., 1990; Hammer et al., 1994). Reported doses for systemic therapy in dogs are 150 mg/m^2 IV, weekly. Local or topical therapy is the more common route of administration in veterinary medicine as intraincisional therapy in spindle cell tumors of dogs and intralesional therapy for sarcoids in horses are reported to have some beneficial biological effect (Stewart et al., 2006; Marconato et al., 2007). 5-FU is available in 50 mg/ml vials.

Antimicrotubule Agents

Microtubules are principally recognized for their role in separating the duplicate set of chromosomes during mitosis, but they also play critical roles in cellular functions during interphase such as intracellular transport, maintenance of cell shape, neurotransmission, and relay of signals between the cell surface and the nucleus. Microtubules are composed of α- and β-tubulin dimers and a dynamic process of polymerization and depolymerization is required for proper microtubule function. Agents that are used clinically to inhibit microtubule function are structurally complex, naturally occurring or semisynthetic compounds that act to interfere with the normal dynamics of microtubule formation.

Vinca Alkaloids: Vincristine and Vinblastine

The vinca alkaloids vincristine (VCR) and vinblastine (VBL) (Figure 44.19) are naturally occurring plant alkaloids from the pink periwinkle plant (*Catharanthys roseus*). The main action of these drugs is to bind a distinct site on tubulin and prevent the formation of microtubules, thus disrupting the mitotic apparatus and resulting in metaphase arrest and cytotoxicity (Tucker et al., 1977; Wilson et al., 1982). The accumulation of mitotic figures in treated cells correlates with both the drug concentration and duration of treatment. Vinca alkaloids enter the cell via simple diffusion and are rapidly taken into cells. These drugs accumulate inside cells with intracellular concentrations of 150- to 500-fold more than extracellular concentrations; intracellular accumulation is greater for VCR than VBL. Resistance to the vinca alkaloids can occur through two distinct mechanisms. Vinca alkaloids are substrates for MDR1/P-glycoprotein and the classic multidrug resistant phenotype secondary to up-regulation of the transporter results in cross-resistance to anthracyclines (DOX), anthracenediones (mitoxantrone), and vinca alkaloids. Additionally, alterations in the binding site on tubulin molecules or increased expression of an alternate tubulin isoform with reduced affinity for the vinca alkaloids can result in reduced binding affinity and cellular resistance (Houghton et al., 1985; Ranganathan et al., 1998). The relative importance of tubulin alterations and expression of different tubulin isoforms to resistance in veterinary medicine has not been explored. The vinca alkaloids are administered by intravenous bolus injection and care must be taken to avoid extravasation, particularly with vincristine which can cause severe soft tissue injury. Following intravenous administration of vinca alkaloids there is a rapid decline in plasma concentration as drug distributes to peripheral tissues and intracellular spaces, followed by a slow elimination phase, primarily characterized by hepatic metabolism and biliary excretion of parent drug and metabolites. The spectrum of antitumor activity differs slightly between vincristine and vinblastine yet the principal toxicities vary dramatically. Vincristine is minimally myelosuppressive at standard doses and is a therapeutic option for neutropenic patients. In humans, a cumulative peripheral neurotoxicity is the principal toxicity following VCR administration, although central nervous system toxicity is possible



vincristine

vinblastine

Figure 44.19 Structures of the vinca alkaloid antitumor drugs vincristine (left) and vinblastine (right).

and has been documented in a dog with a mutation of the *MDR1* gene (Krugman et al., 2012). In contrast, vinblastine is less likely to produce neurotoxicity but is myelosuppressive with neutrophil nadirs occurring between 4 and 7 days after treatment.

Vincristine is most often used as a component of multiagent protocols for lymphoma and is curative in canine transmissible venereal tumor (CTVT) following three weekly doses (Ganguly et al., 2016). Vincristine has also been used to increase peripheral platelet numbers in cases of severe primary immune-mediated thrombocytopenia (IMT) in dogs (Rozanski et al., 2002). Vincristine is generally dosed at 0.5–0.75 mg/m^2 IV, weekly, or as defined by the specific protocol being used. For cases of IMT, the dose of vincristine is 0.02 mg/kg. Vinblastine is most often used in the treatment of canine mast cell tumors, either as a single agent or in combination (Rassnick et al., 2008). Vinblastine doses range from 2.5 to 3.5 mg/m^2 IV every 2 to 3 weeks (Bailey et al., 2008; Vickery et al., 2008). Both drugs are available as 1 mg/ml injectable solutions.

Taxanes

Paclitaxel

Paclitaxel (Figure 44.20) is an antimicrotubule agent that was originally isolated from the Pacific yew tree, *Taxus brevifolia*, in the early 1970s. By stabilizing microtubules and preventing depolymerization the taxanes disrupt normal tubulin dynamics and, similar to the vinca alkaloids, prevent normal chromosomal segregation during mitosis leading to cell death. In human oncology, paclitaxel has established activity in a variety of cancers, including breast cancer, where combinations utilizing paclitaxel have proven to increase survival rates (Simpson and Plosker, 2004). Because of poor solubility, paclitaxel is formulated in a Cremephor EL carrier, which is responsible for hypersensitivity reactions that are common following administration. In dogs, paclitaxel administration has resulted in partial responses in tumors such as osteosarcoma, mammary carcinoma, and malignant histiocytosis (Poirier et al., 2004). However, significant hypersensitivity reactions may still be seen in dogs due to the Cremephore EL carrier even with administration of antihistamines and corticosteroids, which limits its clinical utility. A Cremephore-free paclitaxel (Paccal® Vet CA-1), which is formulated in a water-soluble micellar form, has been evaluated in dogs and is associated with a greatly reduced incidence of hypersensitivity reactions and shows promising clinical benefit (Rivera et al., 2013). The suggested starting dose is 150 mg/m^2 intravenously every 21 days and at this dose the most common toxicities are associated with gastrointestinal toxicity and myelosuppression that are generally mild and manageable (Von Euler et al., 2013). A randomized clinical trial in dogs showed Paccal® Vet to be well tolerated and have superior efficacy compared to lomustine in nonresectable mast cell tumors (Vail et al., 2012).

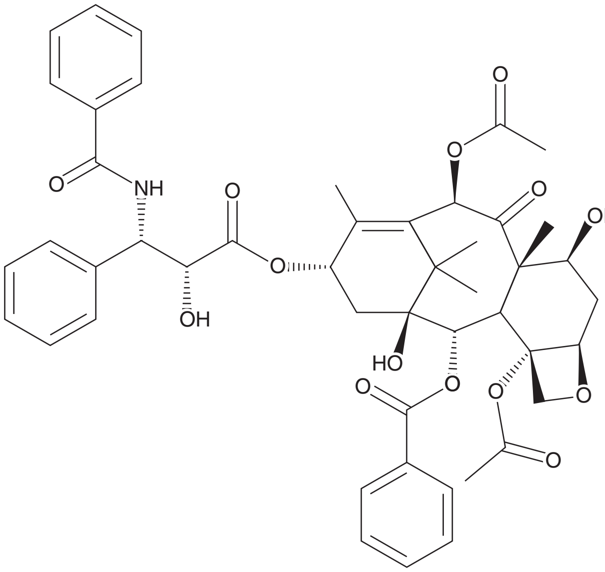


Figure 44.20 Structure of the antimicrotubule agent paclitaxel, originally isolated from the Pacific Yew tree.

The pharmacokinetics of Paccal® Vet has been determined following a single IV dose of 100–150 mg/m^2. A two-compartment model best fit the data with a short distribution phase and an elimination half-life of approximately 3.5 hours. In dogs, clearance values are widely variable but fall within the reported range of clearance values of paclitaxel in humans (Von Euler et al., 2013). Elimination of paclitaxel is primarily through hepatic metabolism via cytochrome P450 enzymes, and oral bioavailability is limited due to a significant first-pass effect and drug efflux by P-glycoprotein (Jibodh et al., 2013). Importantly, at the time of publication, Paccal® Vet CA-1 no longer has conditional approval and no legal marketing status; however, this may likely change in the future and the drug may become available once more, with a different dose recommendation.

Platinum Containing Agents

Cisplatin, carboplatin, and oxaliplatin are cytotoxic compounds that are based on elemental platinum. These drugs resemble alkylating agents in that they can form strong chemical bonds with nucleophiles such as the nitrogen in nucleic acids and sulfur in proteins. While platinum drugs are capable of binding to DNA, RNA, and proteins, the binding to DNA appears to correlate with drug-induced cell killing (Zwelling et al., 1979). All of the clinically useful platinum compounds are bifunctional and capable of producing a covalent cross-link between two nucleophilic atoms of a molecule. Generally,

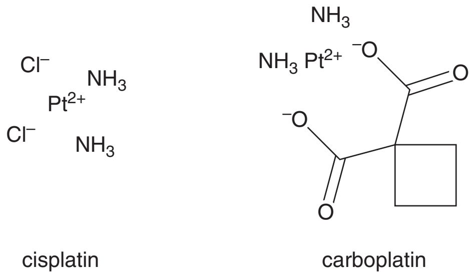

Figure 44.21 Structures of the platinum-containing antitumor agents cisplatin (left) and carboplatin (right).

if the two sites are on the same DNA strand, the lesion is referred to as a *DNA adduct* while *DNA cross-links* are formed by binding sites on different DNA strands. These DNA lesions inhibit DNA replication and transcription and ultimately induce apoptosis. Reactions with water, whereby the chloride groups of cisplatin or carboxylato groups of carboplatin are sequentially replaced with hydroxyl groups in a process termed *aquation*, are important components of the cellular pharmacology of platinum drugs with regard to transport across cell membranes and trapping within the cell. Resistance to the platinum agents can be through cytosolic inactivation of the drug secondary to glutathione conjugation or inactivation from other sulfhydryl-containing groups such as proteins. Increased repair of the DNA damage induced by platinum drugs is another mechanism of resistance and, specifically, increased nucleotide excision repair (NER) is associated with high-level resistance (Parker et al., 1991; Reed, 2001). Cisplatin and carboplatin (Figure 44.21) are both administered intravenously and there is extensive binding to plasma and tissue proteins. Elimination of cisplatin and carboplatin is essentially entirely by renal elimination of bound and unbound forms. There is a strong relationship between carboplatin exposure (AUC) and glomerular filtration rate in humans and cats, and dosing strategies that target a specific AUC based on patient glomerular filtration have been developed for both species (Calvert et al., 1989; Bailey et al., 2004). The pharmacokinetics of carboplatin in dogs has been reported previously (Page et al., 1993).

Cisplatin has been utilized for the treatment of squamous cell carcinoma, osteosarcoma, transitional cell carcinoma, and nasal adenocarcinoma (Knapp et al., 1988; Hahn et al., 1992). Nephrotoxicity is associated with cisplatin administration, which necessitates aggressive fluid diuresis prior to and immediately after drug administration. Standard protocols involve a 4-hour diuresis before, and an additional 2-hour diuresis with normal saline following, the IV bolus of cisplatin. Because of the significant time commitment involved with cisplatin therapy, carboplatin is commonly chosen instead. Additionally, emesis is common in cisplatin-treated patients and antiemetic therapy is commonly required. Doses of cisplatin are generally 50–70 mg/m^2 IV every 3 weeks. Cisplatin is contraindicated in cats due to the development of fulminant pulmonary edema (Knapp et al., 1987).

Carboplatin is often preferred over cisplatin because of reduce incidence of nausea/vomiting and nephrotoxicity. Myelosuppression is the dose-limiting toxicity with carboplatin and the neutrophil nadir typically occurs 14 days following administration. Carboplatin is commonly used in combination with doxorubicin for canine appendicular osteosarcoma as well as a variety of carcinomas. Doses reported for dogs and cats are 300 and 240 mg/m^2 IV every 3 weeks, respectively (Bacon et al., 2008; Kisseberth et al., 2008; Skorupski et al., 2016). As mentioned previously, AUC based dosing is possible in cats utilizing measured glomerular filtration and may provide a rational means of treating patients with preexisting renal dysfunction.

Miscellaneous Drugs

L-Asparaginase

The growth of all cells is dependent upon the availability of nutrients and cofactors that are required for protein synthesis. A long-desired goal of cancer therapy has been to identify differences between normal and neoplastic cells with regard to nutritional requirements that might be exploited. L-asparaginase is one example of a therapy that takes advantage of qualitative differences in the nutritional requirements of tumor cells. L-asparagine is a nonessential amino acid that in synthesized intracellularly by the enzyme L-asparagine synthetase; many tumor cells, and particularly those derived from the lymphoid lineage, are deficient in L-asparagine synthetase and must obtain asparagine by scavenging it from circulation (Haley et al., 1961). Circulating L-asparagine is hydrolyzed by L-asparaginase, producing L-aspartic acid and ammonia as end products and this depletes the tumor cells in L-asparagine, resulting in the induction of apoptosis (Story et al., 1993). The constitutive expression of L-asparagine synthetase in most normal tissues accounts for the modest toxicity seen with asparagine depletion from circulation.

L-asparaginase (Elspar) is derived from *E. coli* and can be administered either subcutaneously, intramuscularly, or intraperitoneally. In humans, the plasma half-life is approximately 30 days and elimination is via metabolic degradation; no pharmacokinetic studies specific to dogs were found.

Although most susceptible tumors will respond with a dramatic reduction in size, resistance to L-asparaginase develops rapidly and most likely reflects outgrowth of populations of tumor cells that have functional L-aspargine synthetase. Side-effects of L-asparaginase administration are not extremely common in dogs but may involve hypersensitivity reactions, particularly with repeated administration of this foreign protein, which can be managed with antihistamines and/or corticosteroids. Other toxicities that are rarer are associated with reduced protein synthesis from reduced asparagine pools; reduce protein synthesis in the liver can result in depleted clotting factors but clinically significant bleeding or thrombosis in dogs following L-asparaginase is extremely rare. Pancreatitis following L-aparaginase has been recognized in the dog (Schleis et al., 2011) and is better characterized in children (Raja et al., 2012). As one of the end products of asparagine hydrolysis is ammonia, a clinically significant hyperammonemia may develop following therapy and, particularly in patients with preexisting hepatic disease, this may result in a syndrome that resembles ammonia encephalopathy (Lyles et al., 2011).

L-asparaginase is utilized exclusively in the treatment of lymphoid malignancies in combination protocols to induce remission or in the treatment of relapsed or refractory lymphoma (Valerius et al., 1997; Saba et al., 2007). There is evidence suggesting that L-asparaginase may best be utilized in the setting of relapsed or refractory disease as time to remission and duration of first remission in treatment-naïve dogs was not significantly different when protocols with and without L-asparaginase were compared (MacDonald et al., 2005).

The dose of L-asparaginase is generally 400 IU/kg IM or SQ or 10,000 IU/m^2 IM or SQ. It is available in vials containing 10,000 IU for parenteral administration.

Bleomycin

Bleomycin is a mixture of glycopeptides in which bleomycin A2 is the predominant species in clinical formulations. Bleomycin is a useful drug in veterinary oncology because of the activity against squamous cell carcinomas and the virtual lack of bone marrow toxicity, making it valuable in multidrug regimens. Bleomycin binds to heavy metals (mainly copper and iron) and the bleomycin–iron complex appears responsible for cytotoxicity through direct damage to DNA by inducing single- and double-strand breaks (Lazo and Chabner, 2001). Cellular uptake of bleomycin is slow and there have not been any transporters associated with active transport; thus, large concentration gradients are maintained between the extracellular and intracellular spaces. The uptake of bleomycin can be enhanced with disruption of the cell membrane such as occurs with electrical permeabilization, and the use of electrochemotherapy with bleomycin has been evaluated and reported to be efficacious in veterinary medicine (Spugnini et al., 2006, 2007; Cemazar et al., 2008). Dose-limiting toxicity with bleomycin is generally pulmonary fibrosis, which appears to be cumulative, and a more common but less significant skin toxicity. The unique locations for bleomycin toxicity appear to be caused by the relative lack of the metabolizing enzyme, bleomycin hydrolase, in pulmonary and skin tissues, resulting in higher drug concentrations in these locations. The pulmonary toxicity is enhanced by increased oxygenation, such as occurs during anesthesia, or in locations of prior chest irradiation (Lazo and Chabner, 2001). Toxic skin effects include desquamation, hyperpigmentation, and pruritic erythema. Bleomycin should be used cautiously in patients with pulmonary disease or renal disease.

Bleomycin is not orally bioavailable and can be administered by the intravenous, subcutaneous, intrapleural, or intramuscular route. In electrochemotherapy protocols it is often injected locally to the tumor or tumor bed. Bleomycin is available as a lyophilized powder in 15-Unit vials for reconstitution and parenteral administration.

Cyclooxygenase Inhibitors

Cyclooxygense-2 (COX-2) has been implicated in human carcinogenesis and clear links between inflammation, COX-2 expression, and development of colon cancer have been identified. These drugs are fully discussed in Chapter 20. In addition, use of nonsteroidal antiinflammatory drugs has demonstrated a clear ability to reduce incidence of tumor development in humans. Similarly, there has been recent effort to utilize COX-2 inhibitors in the treatment of cancers based upon the high degree of expression found in many cancer types and a correlation with higher grade or more aggressive phenotype. In veterinary medicine, COX-2 expression has been identified in numerous tumor types as well, including transitional cell carcinoma of the bladder, prostate tumors, osteosarcoma, squamous cell carcinoma, and ovarian carcinomas (Sorenmo et al., 2004; Borzacchiello et al., 2007; Dore, 2011). Piroxicam (Feldene) has received the most attention in cancer treatment as part of combination protocols involving cytotoxic agents but others, such as carprofen, have been evaluated. The mechanism of action is not fully understood but may involve the inhibition of tumor angiogenesis or direct activation of apoptosis in tumor cells (Wolfesberger et al., 2006). Piroxicam therapy has been extensively evaluated in the treatment of canine transitional cell carcinoma (TCC) in combination with other cytotoxic agents (Mohammed et al., 2006; Greene et al., 2007; Robat et al., 2013). COX-2 inhibition with piroxicam combined with metronomic cyclophosphamide has also been shown to have efficacy in incompletely resected soft tissue sarcomas of dogs (Elmslie et al., 2008). Adverse effects of piroxicam include gastrointestinal ulceration and renal papillary necrosis, effects seen with many of the nonsteroidal antiinflammatory drugs. A complete review of nonsteroidal antiinflammatory mechanisms of action, pharmacokinetics, and toxicity can be found in other chapters.

Corticosteroids

Several of the corticosteroid drugs are used in cancer chemotherapy including prednisolone and dexamethasone. Chapter 29 discusses these drugs in detail. The antiinflammatory effects of corticosteroids can help to alleviate pain in patients with terminal disease, and reduction in brain edema secondary to primary and metastatic tumors occurs, particularly with dexamethasone. In addition, steroids may have a direct cytotoxic effect on neoplastic lymphocytes, which appears to be mediated through the glucocorticoid receptor and results in cellular apoptosis (Baxter et al., 1971; Greenstein et al., 2002). When used as a single agent, however, resistance develops rapidly and may be due to populations of cells lacking the glucocorticoid receptor.

Prednisolone is generally administered in combination protocols for treatment of lymphoma, mast cell tumors, and brain tumors and is well-tolerated in dogs and cats. Dog dosing usually starts at 2 mg/kg or 40 mg/m^2 PO daily with tapering of the dose over 3 to 4 weeks. Cats are generally tolerant to longer-term therapy and may be maintained at 5 mg PO every 24 to 48 hours.

Corticosteroids may also be utilized in the management of some of the side effects of other drugs such as hypersensitivity reactions, radiation recall, or sterile hemorrhagic cystitis. A more complete review of the pharmacokinetics and side effects, particularly with regard to suppression of the hypothalamic–pituitary axis, is provided in Chapter 29.

Tyrosine Kinase Inhibitors

In normal cells, regulation of differentiation, growth, survival, and death is accomplished through signals that originate at the membrane and are transmitted through the cytoplasm to the nucleus. Over the past few years, research into the dysregulation of cell-signaling pathways in cancer has led to a greater understanding of how these pathways lead to uncontrolled cell growth and tumorigenesis. Because many of the alterations in these signaling pathways are similar among various tumor types, they have become promising targets for therapeutic intervention. Among the most well studied components of signaling pathways are the receptor tyrosine kinase (RTK) proteins. These membrane spanning proteins contain an extracellular domain, membrane spanning domain, and an intracellular kinase domain, which functions to phosphorylate key tyrosine residues on themselves and other proteins. Upon binding of a growth factor to the extracellular domain, the receptors form a dimer or oligomer, which brings the kinase domains together and allows for autophosphorylation and activation. This activation is then propagated through “second messengers” in the cell, ultimately activating transcription factors that control expression of genes involved in cell differentiation, proliferation, and survival. Oncogenic alterations in RTKs that result in a constitutively activated protein, even in the absence of the growth factor ligand, and result in uncontrolled signaling, are known to contribute to several human cancers and recent research has begun to characterize similar abnormalities in canine and feline cancers. The two most common approaches to inhibition of RTKs in cancer therapy are the development of monoclonal antibodies (MAbs) and small molecule inhibitors, which competitively inhibit ATP binding and prevent the transfer of the phosphate group (phosphorylation) to tyrosine residues. There are currently two small molecule inhibitors of RTKs which have been evaluated for use in veterinary medicine.

Toceranib

Toceranib (Palladia) (Figure 44.22) is a small molecule inhibitor of the split kinase family of RTKs that includes vascular endothelial growth factor receptor (VEGFR), platelet-derived growth factor receptor (PDGFR), mast/stem cell growth factor receptor (c-KIT), Fms-like tyrosine kinase 3 (FLT3), and colony-stimulating factor 1 receptor (CSF1R). Toceranib has demonstrated activity against mast cell tumors (MCT) and is labeled for use in this tumor type. Activity has also been demonstrated for some sarcomas and carcinomas. In the setting of metastatic or recurrent intermediate or high-grade mast cell tumor, toceranib has an overall biological response rate of approximately 60% (this includes complete responders, partial responders, and those with stable disease) and, interestingly, tumors with documented activating mutation in the c-KIT receptor were twice as likely to respond to therapy as those without mutation (London et al., 2009). The combination of toceranib and vinblastine (a cytotoxic commonly used in MCT) has also been evaluated and shown to be effective,

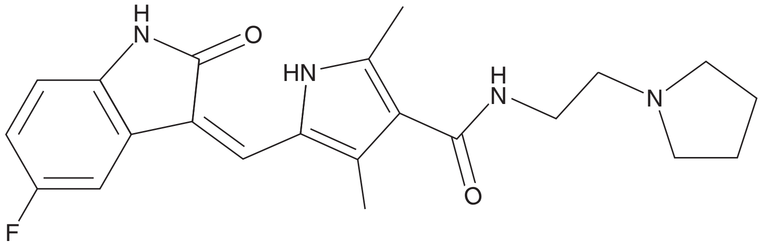

Figure 44.22 Structure of toceranib (Palladia), the first signal transduction inhibitor approved for use in veterinary medicine. Toceranib demonstrates both direct cytotoxic activity through inhibit inhibition of the cKIT oncoprotein on tumor cells as well as antiangiogenic activity through inhibition of vascular endothelial growth factor receptor (VEGFR) and platelet derived growth factor receptor (PDGFR) on tumor vasculature.

although dose reductions in vinblastine were required (Robat et al., 2012). In addition, toceranib has been evaluated in a number of other tumor types and demonstrated a clinical benefit (i.e., complete response, partial response, or stable disease) in anal sac adenocarcinoma, metastatic osteosarcoma, thyroid carcinoma, head and neck carcinoma, and nasal carcinoma (London et al., 2012). Current studies are ongoing and directed at better defining patient populations and tumor types that would benefit from toceranib therapy.

Pharmacokinetic studies of toceranib in dogs have been published and suggest a moderate clearance (1.5 l/kg/h), a large volume of distribution (29 l/kg) suggesting extensive tissue distribution, and a moderate half-life (30 hours) that supports every-other-day dosing (Yancey et al., 2010a). Oral bioavailability is approximately 75% and the majority of the drug and the N-oxide metabolite are excreted in bile with only 7% eliminated in urine (Yancey et al., 2010b). Protein binding is approximately 90% and is independent of plasma drug concentration (Yancey et al., 2010b).

Palladia is metabolized to the N-oxide metabolite through the activity of cytochrome P450 enzymes and thus drug–drug interactions should be considered prior to coadministration of inhibitors or inducer of P450 enzyme activity with regard to increased or decreased exposure to toceranib.

The main toxicities associated with Palladia treatment are gastrointestinal (vomiting/diarrhea) with only mild to moderate neutropenia in most patients. Muscle pain/lameness and protein losing nephropathy have also been reported in dogs receiving toceranib and appear to be cumulative effects. The labeled dose of toceranib is 3.25 mg/kg by mouth every other day and the drug is available as 10, 15, and 50-mg tablets for oral administration.

Masitinib

Masitinib (Kinavet-CA1) is another small molecule inhibitor of c-KIT, PDGFR, and fibroblast growth factor receptor 3 (FGFR3). This drug is also labeled for the treatment of cutaneous mast cell tumors in dogs and has demonstrated a longer time to progression (TTP) and long-term disease control compared to placebo, with a greater effect in tumors that have an activating mutation in the c-KIT receptor (Hahn et al., 2008; Hahn et al., 2010). Toxicities reported with masitinib treatment include gastrointestinal (vomiting/diarrhea), renal (azotemia and proteinuria), hepatic (elevated liver enzymes), and mild to moderate neutropenia. Masitinib is also metabolized by hepatic P450 enzymes and drugs that inhibit P450 activity may increase exposure to masitinib. The initial dose of masitinib is 12.5 mg/kg by mouth, daily with food. Importantly, at the time of publication, masitinib, which was previously conditionally approved, no longer has approval and currently has no legal marketing status. However, this may change and masitinib may become available again to veterinary clinicians in the future.

New Agents

Rabacfosadine

Rabacfosadine (Tanovea CA-1) is a novel, double prodrug of an acyclic nucleotide analog, 9-(2-phosphonylmethoxyethyl) guanine (PMEG). PMEG acts as a competitive inhibitor of DNA polymerases α, δ, and ε, as well as functioning as a substrate for these enzymes, becoming incorporated into DNA, which results in chain termination (Kramata et al., 1998). This leads to S-phase cell cycle arrest and apoptosis. Rabacfosadine selectively accumulates in lymphoid cells where it is converted intracellularly through enzymatic hydrolysis, deamination, and subsequent rapid formation via phosphorylation of the active diphosphate form of PMEG, PMEGpp (Reiser et al., 2008; Vail et al., 2009; Morges et al., 2014). Rabacfosadine is labeled for the treatment of lymphoma in dogs. Activity has been demonstrated in cutaneous T-cell lymphoma (Morges et al., 2014), multicentric lymphoma (Reiser et al., 2008; Vail et al., 2009; Thamm et al., 2017) as well as multiple myeloma (Thamm et al., 2014). A study evaluating the efficacy of rabacfosadine in combination with doxorubicin for treatment-naïve canine lymphoma patients demonstrated that alternating rabacfosadine with doxorubicin provided comparable responses to other standard doxorubicin-based multidrug protocols but required less frequent hospital visits (Thamm et al., 2017). The most commonly reported adverse events following rabacfosadine administration are transient and self-limiting gastrointestinal and hematological toxicity, and 25% or more of dogs may develop dermatopathy, presenting with a wide range of symptoms such as alopecia, otitis externa, ulceration, pyoderma, or excoriations (Morges et al., 2014; Thamm et al., 2014, 2017). Uncommonly, life-threatening or fatal pulmonary fibrosis has been reported as an adverse event and monitoring for this condition is suggested. Additionally, clinical studies of rabacfosadine have often excluded the West Highland white terrier breed because of their predisposition to development of idiopathic pulmonary fibrosis (Heikkila et al., 2011; Heikkila-Laurila and Rajamaki, 2014).

Pharmacokinetic analysis of rabacfosadine in dogs reveals a rapid plasma clearance of parent drug with a half-life of approximately 30 minutes. The cytotoxic PMEG is undetectable in plasma but high concentrations are present in lymphoid cells, while concentrations of the active PMEGpp are nearly 1.5 μM with an intracellular half-life of over 65 hours (Reiser et al., 2008;

Vail et al., 2009). Rabacfosadine (Tanovea-CA1) is available as a 16.4-mg vial for reconstitution and dilution in 0.9% saline and is administered initially at 1 mg/kg as a 30-minute intravenous infusion. Rabacfosadine currently has conditional approval and, as such, may only be used according to the label for treatment of lymphoma in dogs.

Immunosuppressive Drugs

Mark G. Papich

Conditions that require immunosuppressive drugs include skin diseases such as pemphigus, pemphigoid, and lupus-like syndromes. Systemic immune-mediated diseases requiring immunosuppressive drug therapy include immune-mediated hemolytic anemia (IMHA), systemic lupus (SLE), and immune-mediated thrombocytopenia (ITP). For management of some of these disorders, corticosteroids, alkylating agents, cytotoxic drugs, cyclosporine, and gold compounds have been used. Nonsteroidal antiinflammatory drugs (NSAIDs) alone are not usually effective. One of the problems with assessing these medications in veterinary medicine is that there is not enough good quality data to compare drugs, or to understand which one is best for specific conditions. For example, in a systematic review of treatment for IMHA – one of the most important immune-mediated diseases seen by veterinarians – the authors concluded that "This review shows that there are few pieces of high-quality evidence available to inform clinicians managing cases of IMHA in dogs." (Swann and Skelly, 2013).

Glucocorticoids

Glucocorticoids are usually the initial drugs used for treating immune-mediated diseases. They are consistently effective, but have multiple side effects and adverse effects, especially with long-term use. The pharmacology of glucocorticoids is discussed in detail in Chapter 29 and readers are referred to that chapter. Briefly, glucocorticoids exert their action via binding to intracellular receptors, translocating to the nucleus, and binding to receptor sites on responsive genes (Rhen and Cidlowski, 2005; Boumpas et al., 1993), where they modulate the transcription of glucocorticoid-responsive genes (Barnes and Karin, 1997; Barnes, 2001; Hayashi et al., 2004; Rhen and Cidlowski, 2005). By regulating glucocorticoid-responsive genes, protein synthesis is altered, which affects cell function.

Cellular Effects

The mechanism of action for the immunosuppression caused by corticosteroids is complex. In the study by Ammersbach et al. (2006), the authors demonstrated decreased neutrophil migration and survival, decreased cytokines, decreased adhesion expression, and a decrease in the cytotoxic lymphocyte function as well as lymphocyte apoptosis. The dose used in this study in dogs was approximately 2 mg/kg per day for 3 days.

Corticosteroids increase the circulating numbers of mature neutrophils. There is a release of cells from the marginal pool of neutrophils and decreased migration and egress into inflammatory sites. This effect is attributed to decreased expression of adhesion molecules, reduced adherence to the vessel endothelium, and reduced diapedesis from the vessels. Subsequently, there is decreased movement of inflammatory cells into tissues in response to chemotactic stimuli.

Glucocorticoids also affect many functions of macrophages. They suppress the function of macrophages and decrease the inflammatory response, generation of cytokines, and the ability of macrophages to process antigens. They also inhibit phagocytosis by macrophages.

Glucocorticoids affect leukocyte traffic more than cellular function. Corticosteroids decrease the numbers of lymphocytes in the peripheral circulation – caused by a redistribution of circulating lymphocytes – depress lymphocyte activation, and decrease participation of lymphocytes in inflammation. T cells are affected more than B cells. Because B cells are more resistant to the immunosuppressive effects of glucocorticoids, there is minimal effect on immunoglobulin synthesis. However, high corticosteroid doses will decrease immunoglobulin levels, probably because of increased catabolism, as well as through the secondary effects to suppress accessory cells and cytokine synthesis. At antiinflammatory doses, glucocorticoids do not decrease an animal's ability to mount a normal immune response (e.g., from vaccinations) (Nara et al., 1979). Other effects of glucocorticoids include inhibited release of inflammatory cytokines

Veterinary Pharmacology and Therapeutics, Tenth Edition. Edited by Jim E. Riviere and Mark G. Papich.

Companion Website: www.wiley.com/go/riviere/pharmacology

from leukocytes (e.g., IL-1, TNF-α, prostaglandins) and decreased expression of cytokines from lymphocytes (e.g., IL-2).

Immunosuppressive Effects

It is difficult to separate the antiinflammatory from the immunosuppressive effects of glucocorticoids. For a complete review of these effects the articles by Cohn (1991) and Barnes (2006) should be consulted. For immune-mediated disorders (e.g., autoimmune skin disease, IMHA, and thrombocytopenia, SLE, immune-mediated polyarthritis) glucocorticoids suppress the immune system response to alleviate clinical signs. In a study in which various treatments for IMHA were examined, corticosteroids alone were as effective as combination treatments (for example, with azathioprine, cyclophosphamide, etc.) (Grundy and Barton, 2001).

Choice of Drugs

For long-term therapy, intermediate-acting steroids (prednisone, prednisolone) are used most often because they can be administered on an every-other-day (EOD) basis. However, injections of dexamethasone are often used for acute, short-term treatment. There are no demonstrated differences in response between dexamethasone and prednisone/prednisolone for acute treatment, but long-term adverse effects may be less for the shorter-acting agents such as prednisone/prednisolone.

Doses

The immune-suppressing effects require higher dosages of corticosteroids than are necessary for antiinflammatory therapy (often by a factor of at least 2-fold), although dose-response relationships have not been fully studied in veterinary medicine. In one study in which the authors documented response to treatment of IMHA, the starting dose of prednisolone was 2 mg/kg per day, followed by a tapering schedule (Piek et al., 2008). In a systematic review of treatment for IMHA, the authors found that glucocorticoids alone will result in a successful outcome in a high proportion of cases, although there is no consensus on the drug dose or duration of treatment (Swann and Skelly, 2013).

Initial (induction) dosage regimens employ daily doses of 2.2 to 6.6 mg/kg (prednisolone or prednisone). Doses greater than 6 mg/kg are rarely used in dogs. Initial doses generally are in the range of 2–4 mg/kg/day. One study reported that the optimal induction doses for skin diseases were 4.4 mg/kg/day for dogs and 6.6 mg/kg/day for cats. A systematic review of treatment outcomes from IMHA in dogs concluded that prednisolone greater than 2 mg/kg every 12 hours are likely to result in unacceptable adverse effects without apparent improvement in short- or long-term outcomes. After an induction period, if the patient responds favorably, the dose may be decreased by approximately 50%. Eventually, one should attempt to maintain the patient on this low dose on an every-other-day EOD basis. Some diseases are slow to respond and a reduction of doses should be performed on a gradual and prolonged schedule. For example, lowering the dose based on an evaluation every 2–4 weeks may be necessary. Eventually, for immune-mediated disease, maintenance doses of 1 mg/kg, EOD are possible but higher doses or adjunctive therapy may be necessary in individual patients.

Adverse Effects

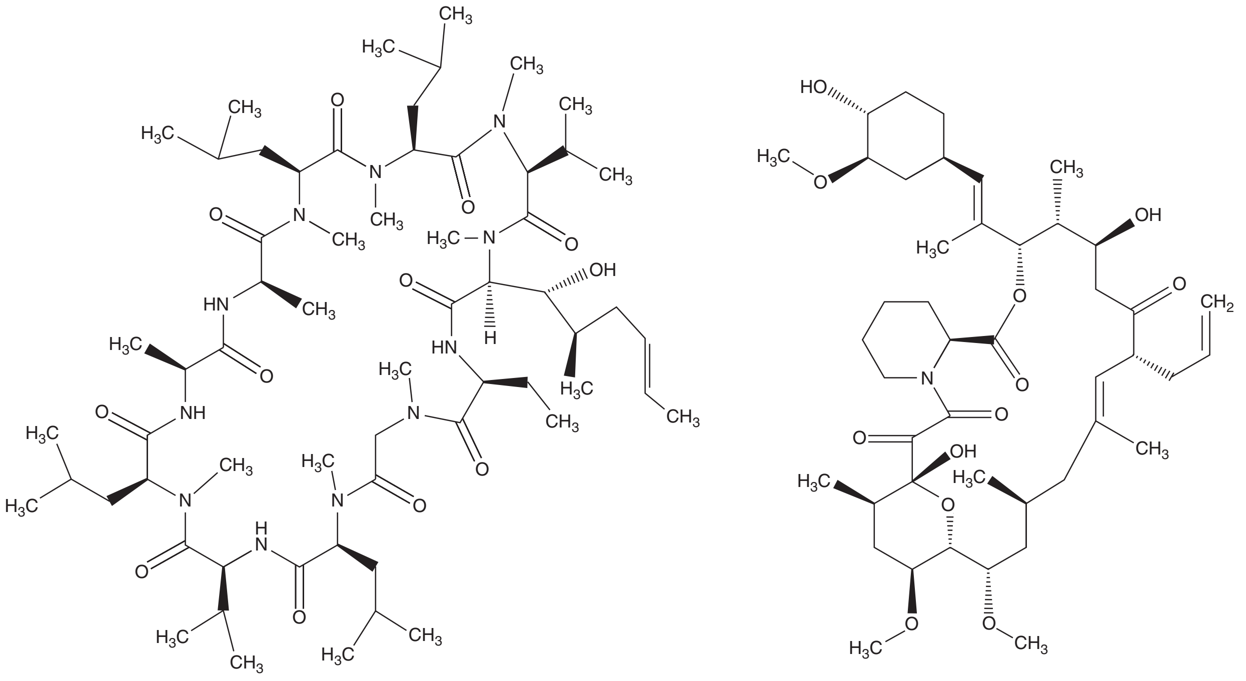
Side effects associated with treatment are discussed in Chapter 29. These effects are not necessarily reasons for discontinuing therapy, and include polyuria/polydipsia, increased appetite (polyphagia), and behavior changes (increased restlessness for example). Adverse effects from immunosuppressive doses of corticosteroids include risk of infectious diseases, adrenal suppression, pancreatitis, delay of healing, catabolic effects on muscle and connective tissues, and hepatopathy.

Rationale for Every-Other-Day Therapy

If a glucocorticoid is used that has a duration of action of 12–36 hours (intermediate-acting), the hypothalamic–pituitary–adrenal (HPA) axis has an opportunity to recover before the next dose. It is important that one chooses a glucocorticoid that does not have a long duration of action for EOD therapy – for example, dexamethasone is unacceptable because its duration is at least 36–48 hours. After 1 mg/kg every 48 hours of prednisolone, adrenocorticotropic hormone (ACTH) was suppressed in dogs for 18 to 24 hours, and returned to normal until the next scheduled dose (Brockus et al., 1999). EOD therapy will minimize, but *will not prevent* adrenal atrophy, and other adverse effects such as those on the immune system and the effects on metabolism.

Cyclosporine

Cyclosporine is a fat-soluble, cyclic polypeptide with immunosuppressive activity (Figure 45.1). It was derived from the soil fungus *Tolypocladium inflatum*. The proper spelling of the name has been a source of confusion. The US adopted name (USAN) is *cyclosporine*. The British Approved Name (BAN) is *ciclosporin*, which is the same as the International Nonproprietary Name (INN). Previously used names are *cyclosporin* and *cyclosporin A*.



Cyclosporine

Tacrolimus

Figure 45.1 Structure of cyclosporine (left) and tacrolimus (right).

The designation of "A" after the name is no longer necessary. It has been an important drug used in humans, primarily to produce immunosuppression in organ transplant patients. It has gained recognition for veterinary use because of availability of a veterinary formulation of cyclosporine (Atopica). The veterinary product is FDA-approved for both dogs and cats. A review published in 2014 (Archer et al., 2014) provides details of previous studies, pharmacokinetics, and studies in dogs.

Cyclosporine binds to a specific cellular receptor on calcineurin and inhibits the T-cell receptor-activated signal transduction pathway by suppressing the nuclear factor of activated T cells (NFAT) (Figure 45.2). Particularly important are its effects to suppress interleukin-2 (IL-2) tumor necrosis factor-α (TNF-α) and other cytokines, and block proliferation of activated T lymphocytes. The action of cyclosporine is more specific for T cells as compared to B cells. It has little effect on humoral immunity. One important advantage in comparison to other immunosuppressive drugs – especially corticosteroids – is that it does not cause significant myelosuppression or suppress nonspecific immunity.

Clinical Use in Dogs

Cyclosporine has been used for a number of diseases in veterinary medicine and since the introduction into veterinary medicine over 10 years ago, the number of potential uses, particularly in dogs and cats, has increased substantially. Many of these diseases have been dermatological, as reviewed by Robson and Burton (2003). In dogs, when used in the treatment of perianal fistulas, (Mathews and Sukhiani, 1997; Griffiths et al., 1999) an 85% healing rate was found in one study (Mathews et al., 1997) (2.5–6 mg/kg/day); in sebaceous adenitis, good response was reported in one case (Carothers et al., 1991); and in idiopathic sterile nodular panniculitis, excellent results were seen in two reported

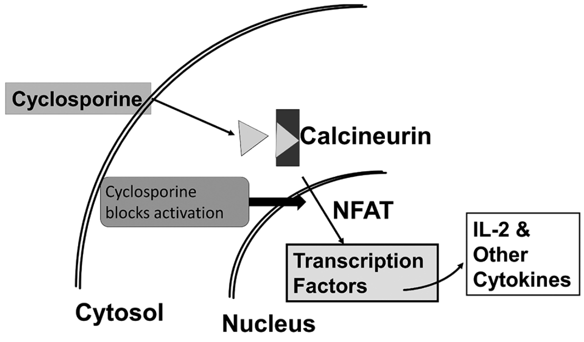


Figure 45.2 Mechanism of action of cyclosporine. Cyclosporine enters the cytosol, where it binds and inhibits calcineurin at a specific receptor site. By inhibiting calcineurin, the movement of the nuclear factor of activated T cells (NFAT) is prevented from entering the nucleus. Without the action of NFAT, transcription factors that produce cytokines is inhibited. (See text for additional details.) Tacrolimus is also capable of inhibiting calcineurin, but at a different binding site.

cases, which were followed for 6 months following discontinuance of the cyclosporine (Guaguère, 2000).

Immune-mediated Diseases

Cyclosporine has been used for treatment of a variety of immune-mediated diseases that include IMHA, inflammatory bowel disease (IBD) (Allenspach et al., 2006), immune-mediated polyarthritis (Rhoades et al., 2016), and aplastic anemia (AA). For some diseases there is only anecdotal accounts of successful outcomes with cyclosporine, and for others (e.g., IMHA) the evidence is of such poor quality that conclusions cannot be made.

For treating immune-mediated skin diseases, the results from pilot studies for treating pemphigus foliaceous in dogs have been disappointing (Rosenkrantz et al., 1989). It did not help any patients with mycosis fungoides. In a study in which five dogs with pemphigus foliaceous were treated, there was little benefit (Olivry et al., 2003a). The dogs with pemphigus foliaceous were initially treated with the “atopy dose” of 5 mg/kg/day. If there was no response the dose was increased to 10 mg/kg/day. At the end of the trial, it was concluded that at 5–10 mg/kg/day cyclosporine was unable to produce complete remission in any of the five dogs. In a case study of immune-mediated polyarthritis in dogs (Clements et al., 2004), dogs were treated with prednisolone and various other immune-modifying drugs. Three dogs treated with cyclosporine at 5 mg/kg per day did not respond.

Atopic Dermatitis

In people it has been used successfully for treatment of atopic dermatitis (Camp et al., 1993). Because of this efficacy, the use of cyclosporine for treating canine atopic dermatitis was initially investigated in a pilot study of 14 dogs (Fontaine and Olivry, 2001), and subsequently in larger controlled studies (Olivry et al., 2002a, 2002b). The evidence for recommending cyclosporine was summarized by a task force (Marsella and Olivry, 2001) and an evidence-based review (Olivry et al., 2003b). In another trial of 30 dogs treated with cyclosporine (5 mg/kg/day) or prednisolone (0.5 mg/kg/day), the efficacy of cyclosporine was not statistically different than prednisolone (Olivry et al., 2002a). Reductions in mean lesion scores were 60% and 59% in prednisolone and cyclosporine groups, respectively. Reduction in mean pruritus scores were 81% and 78% in prednisolone and cyclosporine groups, respectively. In another published study from the same author (Olivry et al., 2002b), 91 dogs with atopic dermatitis were treated with cyclosporine and compared to placebo. Two doses were examined, 2.5 mg/kg/day and 5 mg/kg/day. There was a dose-dependent effect. Dogs treated with 5 mg/kg had statistically significant reduction in pruritus scores (45%) and skin lesions (67%). The dose of 2.5 mg/kg was not statistically different from placebo. Some dogs may benefit from less than once-daily administration, as shown in another study (Steffan et al., 2003). In this study, administration of cyclosporine (5 mg/kg) was compared to methylprednisolone (0.75 mg/kg) for treatment of canine atopic dermatitis. The response was not different between the drugs, but there was an overall better assessment of efficacy and more gastrointestinal problems in dogs treated with cyclosporine. In the cyclosporine-treated dogs, the dose was started at 5 mg/kg/day for 4 weeks, but eventually half of the dogs were adjusted to an EOD dose, and one-quarter of the dogs were given cyclosporine at 5 mg/kg only twice a week.

Clinical Use in Cats

In August 2011, a cyclosporine oral solution (Atopia) was the first drug approved by the FDA for treating allergic dermatitis in cats. Capsules also can be used and one 25-mg capsule has been used for a dose of 25 mg/cat, once daily. The FDA-approved dose is 7 mg/kg per day, which is higher than the canine dose. Higher doses are needed because of the more variable absorption in cats compared to dogs. Other uses for cats include immunosuppression for kidney transplantation (Mathews and Gregory, 1997) at a dose of 3–4 mg/kg q 12 h. It also has been used to treat inflammatory diseases in cats, including stomatitis and eosinophilia granuloma complex (Guaguère and Prèlaud, 2000; Vercelli et al., 2006). For treatment of pemphigus foliaceous in cats it was more effective than in dogs. At a dose of 5 mg/kg per day, it was effective in some cats and steroid sparing (Irwin et al., 2012).

Formulations and Pharmacokinetics

The pharmacokinetics of cyclosporine are complicated because of the differences between dosage forms, presence of many metabolites, influence of drug interactions, and variability in oral absorption. The formulation called *Sandimmune* was used for many years but was absorbed inconsistently and is not used today. The common human formulation is a microemulsion called *Neoral,* which has a much more consistent rate and extent of absorption that is less affected by factors such as feeding than Sandimmune (Lown et al., 1997). There are now over 20 human generic formulations of this formulation. There is no evidence available to show that the human generic formulations are bioequivalent to the brand-name product in dogs and cats. The introduction in late 2003 of Atopica represents the first oral veterinary formulation of cyclosporine. The formulation is exactly the same as Neoral microemulsion (absorption, kinetics, and dissolution), except that there is a greater variety of capsule sizes available (10, 25, 50, and 100 mg) for veterinary use. Compounded formulations can have variable strength and are not recommended for clinical use in dogs and cats.

The pharmacokinetics of cyclosporine in treated animals has been examined (Steffan et al., 2004). Cyclosporine is metabolized in the intestine and liver. Twenty-five to thirty metabolites have been identified. The prehepatic intestinal enzymes account for significant metabolism of cyclosporine (Wu et al., 1995), and systemic absorption in dogs is only 20–30% (Myre et al., 1991). Systemic absorption in cats is similar at 25–29% (Mehl et al., 2003). The intestinal metabolism by cytochrome P450 enzymes (CYP) and the efflux caused by intestinal p-glycoprotein (P-gp) account for most of the loss in systemic availability after oral administration. Drug enzyme inhibitors can inhibit the presystemic metabolism and produce an increase in systemic availability of cyclosporine (see Section Drug Interaction). For example, 5–10 mg/kg of ketoconazole once daily can decrease the dose of cyclosporine because clearance is reduced by 85% (Myre et al., 1991).

Administration

As in the clinical trials cited in this chapter, the effective dose for treating dermatitis in dogs has been 5 mg/kg/day. There may be a delay in response when cyclosporine is initiated for as long as 4–6 weeks and some dermatologists administer corticosteroids for the first 2 weeks when initiating treatment. Some clinicians have been able to lower the dose, or administer the dose every other day, and still maintain clinical remission. Approximately half of treated dogs can be maintained by increasing the dose interval.

Although clinical studies evaluating efficacy for treating immune-mediated diseases in dogs or cats are very limited, cyclosporine has been used for diseases listed in Sections Clinical Use in Dogs and Clinical Use in Cats. For these conditions it is generally assumed that higher doses are needed – generally in the range of 10 mg/kg every 12 hours oral. At these doses, cyclosporine consistently suppressed cytokine expression from activated T cells in dogs for a duration of 12 hours (Fellman et al., 2015). The same authors found that at a lower dose of 5 mg/kg once daily in dogs produced a more variable response and inconsistent suppression of activated T cells (Archer et al., 2011).

Monitoring

For organ transplantation in people, doses of 5–10 mg/kg/day are used to achieve targeted whole blood concentrations of 150–400 ng/ml. In people, dosages are adjusted to meet the needs of the individual patient on the basis of clinical response and monitoring trough plasma concentrations. For organ transplantation in cats (Mathews and Gregory, 1997) a dose of 3 mg/kg q 12 h was used to achieve trough blood concentrations of 300–500 ng/ml. For organ transplant in dogs, 10 mg/kg q 12 h to achieve concentrations of 500–600 ng/ml has been used (Mathews et al., 2000).

A report on treating perianal fistulas in dogs (Mathews and Sukhiani, 1997) found that an average dose of 6 mg/kg q 12 h was needed to achieve a targeted blood concentration of 400–600 ng/ml. However, this recommendation was later modified to 2.5–6 mg/kg/day. The most common dose for treating perianal fistulas is 3 mg/kg q 12 h.

Steffan and colleagues (2004) found that when administering approved doses to dogs with atopic dermatitis, routine monitoring of blood cyclosporine concentrations was not necessary. When animals were administered a dose of 5 mg/kg/day, there did not appear to be a strong correlation between blood concentration achieved and clinical response. It is also difficult to interpret blood concentration monitoring results because no therapeutic range has been established for dogs and cats. Nevertheless, because of wide individual variation in cyclosporine pharmacokinetics, monitoring blood concentrations is sometimes used to determine if the lack of therapeutic response is caused by inadequate oral absorption, rapid metabolism, or poor compliance by the pet owner. Monitoring can sometimes be helpful to identify why patients may be nonresponders. Effective treatment has been reported, even when trough blood concentrations are low. However, according to one paper, clinical benefits have not been observed when trough concentrations have fallen below 50 ng/ml; therefore, blood testing of patients failing therapy was suggested to reveal inadequate dosing (Robson and Burton, 2003).

One must be cognizant of the assay used when monitoring cyclosporine. Plasma values will be lower than whole-blood assays because as much as 50–60% and 10–20% of the dose is concentrated in erythrocytes and leukocytes, respectively. Nonspecific immunoassays will report higher values than a more specific (monoclonal or HPLC) assay. Despite the hypothesized higher specificity when using the monoclonal assay, important discrepancies between these assays and the more specific HPLC assay have been reported (Steimer, 1999).

If trough samples are monitored (to detect the lowest point during the dose interval), samples are collected immediately before the next scheduled dose (Figure 45.3). However, trough concentrations can be low because of the short half-life and may not correlate with clinical response. Effective treatment has been reported, even when trough blood concentrations are low. If peak samples are monitored (to detect the maximum concentration) blood sample monitoring is done by collecting a 2-hour sample (C2), which correlates

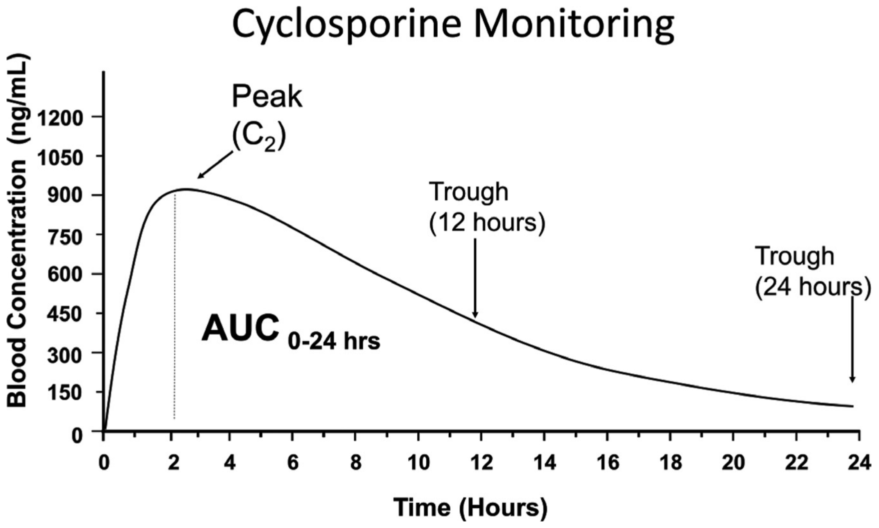

Figure 45.3 Hypothetical blood concentration versus time curve for cyclosporine administration to animals. The peak concentration typically occurs at 2 hours in most animals and can be used to monitor peak effects. This concentration (C_2) is correlated with the total area-under-the-curve (AUC) and is associated with pharmacodynamic effects (see text). If monitoring is performed by collecting a trough sample, there can be differences between the 12 hour sample (with twice-daily dosing) compared to the 24 hour sample (with once-daily dosing).

better with the area-under-the-curve (AUC) than the trough concentration (Figure 45.3). A 2-hour sample collected from dogs was able to detect the peak response, which correlated with immunosuppressive effects better than trough concentrations (Fellman et al., 2015). This confirmation in dogs agrees with evidence in people that a C2 blood sample value correlates better with clinical results than trough samples (Levy et al., 2002; Nashan et al., 2002). If monitoring is performed using a 2-hour sample, anticipate that the drug concentration at 2 hours will be approximately twice as high compared to the levels at 12 hours. The peak concentration to dose ratio in dogs is 179 ± 56. Therefore, at a dose of 5 mg/kg, the average peak concentration is 895 ng/mL with high variability of 31% coefficient of variation (Archer et al., 2014).

Adverse Effects and Precautions

Cyclosporine can cause vomiting, diarrhea, anorexia, secondary infections, and gingival hyperplasia (Table 45.1). Hyperplastic skin lesions have occasionally developed in dogs treated with cyclosporine (Favrot et al., 2005). Papillomavirus can be detected in some skin lesions. Tremors or shaking have been observed in dogs administered high doses. These events are rare and usually not a problem as long as doses are kept within accepted limits.

Table 45.1 Adverse reactions to cyclosporine reported in animals

- Cats: adverse events
  - Anorexia (most common)
  - Vomiting
  - Weight loss, depression
- Dogs: adverse events
  - Vomiting (most common)
  - Diarrhea
  - Depression
  - Lethargy
  - Pruritus
  - Anorexia
  - Increased liver enzymes
  - Gingival hyperplasia

The most common clinical problem with cyclosporine in dogs and cats that has been cited (Olivry et al., 2002a, 2002b, 2003b; Steffan et al., 2003; Heinrich et al., 2011), or detected in the trials conducted by the drug manufacturer (Novartis), is gastrointestinal problems. Vomiting, anorexia, and diarrhea are consistently the most common adverse effect reported, but in some patients may improve several days after initiating treatment. But, in some patients, it has led to discontinue the medication. When anorexia and vomiting are observed, veterinarians have tried various interventions such as lowering the dose, or administration of the dose with some food. Feeding will reduce the amount of cyclosporine absorbed in dogs by 15–20%, but it is unlikely that this decrease will be severe enough to affect efficacy. Keep in mind that some animals may refuse to eat their food if the drug is mixed in with their diet.

Nephrotoxicity, once a problem with older forms, is rare with current formulations. Secondary malignancies because of decreased immune surveillance are a possible complication to long-term therapy but have not been reported in dogs or cats.

Increased risk of toxoplasmosis has been a concern from cyclosporine administered to cats (Lappin et al., 2015). At a dose of 7.5 mg/kg/day (label dose), for an extended (long) interval, cyclosporine increased the severity of *Toxoplasma gondii* infection in naïve (seronegative) cats, but not in cats previously exposed (seropositive) to *Toxoplasma gondii*, and did not activate oocyst shedding in cats that had been previously exposed. Seronegative (naïve) cats may be at risk for developing clinical toxoplasmosis if they are infected while receiving cyclosporine treatment. Other safety concerns in cats were addressed by the manufacturer or in other studies (Roberts et al., 2014). Safety of cyclosporine in cats at high doses for 6 months was assessed, with the conclusion that it is safe and well tolerated.

Glucose metabolism has been studied in dogs (Kovalik et al., 2011). Cyclosporine will negatively affect glucose homeostasis in some animals. The mechanism is via decreased insulin secretion and possibly insulin resistance, but the clinical significance is unclear. Cyclosporine may increase platelet hypercoagulability, which may be a concern when it is used to treat IMHA in dogs (this disease has been associated with thromboembolism). Cyclosporine administration increases thromboxane (TXA_2), which can trigger platelet aggregation and vasoconstriction (Thomason et al., 2012, 2016). Administration of aspirin to dogs will prevent the cyclosporine-induced increase in TXA_2 (Thomason et al., 2016).

Drug Interactions

Several drugs may interact with cyclosporine. These drugs include ketoconazole, itraconazole, fluconazole, erythromycin, and diltiazem. All these drugs can potentially increase concentrations of cyclosporine in animals. For example, coadministration of ketoconazole to treat secondary fungal infections will substantially decrease metabolism of cyclosporine (Myre et al., 1991). Ketoconazole has been used deliberately to reduce the need for cyclosporine in some investigations (Patricelli et al., 2002) and doses have been reduced to one-third of the original dose when administered with ketoconazole. In one study with cyclosporine in the treatment of perianal fistulae, the dose of 1 mg/kg cyclosporine combined with 10 mg/kg ketoconazole was used. The author felt that a dose of 0.5 mg/kg combined with 10 mg/kg ketoconazole also could be used (Mouatt, 2002). In people, grapefruit juice will increase concentrations of cyclosporine because of inhibition of metabolizing enzymes. However, the dose of grapefruit required to produce a similar effect in dogs is very high (41 capsules) and not clinically practical (Hanley et al., 2010). Cyclosporine also is an inhibitor of one of the membrane transport proteins P-glycoprotein. It can inhibit transport of ivermectin and increase risk of ivermectin toxicity in dogs.

Ophthalmic Use.

Keratoconjunctivitis sicca: Cyclosporine (Optimmune) is approved to increase tear production in dogs with keratoconjunctivitis sicca (KCS). Success rates are high. Topical cyclosporine has also been used to treat other immune-mediated diseases of the eye. It is available as a 0.2% ophthalmic ointment.

Anterior uveitis: Cyclosporine intraocular implants have been developed by an ophthalmologist at North Carolina State University (Gilger et al., 2006). These implants are administered to horses to treat anterior uveitis. This method of treatment slowly releases the medication and can produce a long-term sustained therapeutic effect.

Tacrolimus, Pimecrolimus, and Sirolimus (Rapamycin)

Tacrolimus (Prograf) is a macrolide antibiotic produced by *Streptomyces tsukubaensis* (Figure 45.1). It is approved for use in people as 1 and 5-mg capsules and injection. This drug has similar immunological effects on lymphocytes as cyclosporine but is much more potent. Like cyclosporine, it binds to an intracellular receptor that inhibits IL-2 gene expression in T-helper lymphocytes, although the binding site is different than cyclosporine. It also may bind to receptors that inhibit expression of other cytokines. Most experience with tacrolimus has been in experimental studies. It has not been used systemically in veterinary medicine and may produce unacceptable adverse effects in dogs.

Tacrolimus (Protopic) has been used topically in dogs with some dermatoses. Systemic absorption is so low that it is safe for topical administration to dogs. More recently, pimecrolimus has been used in people as a topical treatment for atopic dermatitis. Pimecrolimus (Elidel) is available as a 1% cream. There is minimal systemic absorption of pimecrolimus after application.

Sirolimus, previously known as rapamycin, is similar in structure to tacrolimus, but with different action on the regulatory pathways. It is a macrocyclic lactone produced from the fungus *Streptomyces hygroscopicus*. It has a unique mechanism of action, and actions that are distinct from tacrolimus. Sirolimus inhibits the function of a specific protein kinase known as the mammalian target of rapamycin (mTOR, also called the mechanistic target of rapamycin). This pathway responds to growth factors and is responsible for cell proliferation. The immunosuppressive properties are caused by inhibition of T-lymphocyte activation and proliferation through the IL-2 pathway. It can inhibit cytokine and growth factor pathways and has been used to prevent transplant rejection in people. Although sirolimus has been used for immunosuppression to prevent transplantation graft rejection, more recently it has been explored for cancer protocols.

The limitation for the use of sirolimus in dogs has been toxicity. When administered to experimental dogs undergoing renal transplantation procedures, the dose of 2 mg/kg produced severe toxicosis that included severe gastrointestinal toxicity with mucosa necrosis, submucosa vasculitis, and death. Even at lower doses of 0.5 mg/kg toxicosis was observed. At lower doses of 0.05 mg/kg IV and 0.1 mg/kg IM there was no toxicity, but insufficient immunosuppression. An additional concern is the tissue irritation and abscesses that have been observed in dogs from SC and IM injection. Subsequently, further studies with sirolimus have been conducted at low doses administered by the oral route (Larson et al., 2016). In a pharmacokinetic study of 0.1 mg/kg oral, the half-life was 38 hours after a single dose and 100 hours after multiple doses and the pharmacokinetics were highly variable among dogs (Larson et al., 2016). Clearance also was affected by multiple administration. The concentrations achieved at this dose may be sufficient for cytostatic and antiangiogenic effects in cancer treatment, but may not be sufficient to produce immunosuppression. More work is needed on this agent to determine the optimum safe and effective dose for animals.

Oclacitinib (Apoquel®)

Oclacitinib was approved by the US FDA in May 2013 for control of pruritus in dogs associated with allergic dermatitis and atopic dermatitis (Cosgrove et al., 2013a, 2013b). It is administered as a tablet, at a dose of 0.5 mg/kg (0.4–0.6 mg/kg, with or without food), initially on a twice-daily schedule for the first 14 days, then it is intended to be tapered to a once-daily administration. The tablet size is 3.6, 5.4, or 16 mg.

Mechanism of Action and Activity

Oclacitinib has a unique mechanism of action that acts to inhibit proinflammatory cytokines. It inhibits cytokines involved with pruritus in dogs that are dependent on the Janus kinase (JAK) enzyme (Gonzales et al., 2014). It inhibits preferentially the JAK1 enzyme activity over JAK2 or JAK3, with a 1.8-fold selectivity over JAK2, and 9.9-fold selectivity over JAK3. This preferential activity is important because JAK2 is involved with hematopoiesis and high doses of oclacitinib could suppress hematopoiesis. Of significance for atopic and allergic dermatitis treatment is that oclacitinib inhibits the IL-31 cytokine function and reduces IL-31 induced pruritus in dogs. It also may inhibit the function of other proinflammatory cytokines such as IL-2, IL-4, IL-6, and IL-13 that may be involved with allergy.

Use in dogs: In studies of dogs with atopic dermatitis treated with oclacitinib, the efficacy was 66% and 49% as assessed by pet owners and veterinarians, respectively, and 67% in a study with allergic dermatitis. This was significantly better than placebo and 86% of dogs were withdrawn from the placebo arm of the study. Oclacitinib also was shown to have equal efficacy as prednisolone in dogs, with an onset of efficacy of both treatments in as little as 4 hours (Gadeyne et al., 2014). When atopic dogs were treated with either cyclosporine or oclacitinib, the oclacitinib-treated dogs had a faster onset of action and lower frequency of gastrointestinal problems compared to cyclosporine (Little et al., 2015).

Use in cats: At this time, there is only limited information on use in cats. Some veterinarians have used oclacitinib in cats and reported (anecdotally) a beneficial response. However, oclacitinib is not as potent in cats as in dogs and higher doses may be necessary to achieve the same degree of JAK inhibition. Safety at higher doses has not been established in cats.

Pharmacokinetics

It is rapidly absorbed (89% bioavailability) and reaches a peak in less than 1 hour, producing a quick response after administration (Collard et al., 2014). The rapid onset of action distinguishes it from some of the other products currently used for treatment of atopic dermatitis. After absorption, the half-life is approximately 3–5 hours in dogs (Collard et al., 2014). Pharmacokinetics were not affected by feeding or breed of dog.

Safety and Adverse Effects

During the field study reported to the FDA for approval, there was a low rate of adverse reactions (diarrhea 2.3–4.6%, vomiting, 2.3–3.9%), which were not different from the placebo and usually resolved after initial dosing. In a published study (Cosgrove et al., 2013b) there was a 9.2% incidence of vomiting and 6% incidence of diarrhea in 283 dogs. Treated dogs had decreased leukocytes and serum globulin compared to placebo group. In field trials there have been isolated cases of demodicosis, pyoderma, pneumonia, and mast cell tumor or other neoplasms, but it is not known if these were associated with the medication.

Dermatologists have used oclacitinib with other medications such as corticosteroids, cyclosporine, and other systemic agents but published safety information when administered with these agents is not available. Safety has not been evaluated in breeding animals or during pregnancy.

Cyclophosphamide (Cytoxan®)

Cyclophosphamide is one of the nitrogen mustards and is one of the most potent immunosuppressive drugs available. More details on the pharmacology of cyclophosphamide can be found in Chapter 44.

Mechanism of Action

The immunosuppressive effects of the nitrogen mustards can be attributed to the cytotoxic effect on lymphocytes caused by damage to DNA. Cyclophosphamide is metabolized initially to 4-hydroxyphosphamide and then at target sites metabolized spontaneously (nonenzymatically) to active compounds acrolein and phosphoramide mustard. Phosphoramide mustard is responsible for alkylating bases on the DNA molecule. Because of the cytotoxic action on lymphocytes, it can directly suppress B-cell activity and antibody formation. B cells are affected more than T cells because their rate of recovery from an alkylating agent is slower.

Adverse Effects

Cyclophosphamide is a potent immunosuppressive drug with a high risk of myelosuppression. In dogs the most serious toxic effect is bone marrow suppression, which can lead to secondary infections, thrombocytopenia, and anemia. Another adverse effect is sterile hemorrhagic cystitis. The incidence has been estimated to be as high as 24% in treated dogs and 3.7% in treated cats. The injury to the urinary bladder is caused by the toxic effects of metabolites on the bladder epithelium (especially acrolein) that are concentrated and excreted in the urine. Various strategies have been used to decrease the injury to the bladder epithelium. Corticosteroids are usually administered with cyclophosphamide to induce polyuria and decrease the toxic effect of the drug on the epithelium. In people, and occasionally in dogs, the drug mesna (Mesnex, mercaptoethanesulfonate) has been used to prevent drug-induced cystitis. Mesna provides free active thiol groups to bind metabolites of cyclophosphamide in the urine. Another therapy that has been used to reduce hemorrhagic cystitis is the administration of furosemide. In a study of 216 cases (Charney et al., 2003), there was less hemorrhagic cystitis when furosemide was administered concurrently, compared to cyclophosphamide alone. The dose of furosemide used was 2.2 mg/kg IV administered at the time of cyclophosphamide administration.

Cats are more resistant to hemorrhagic cystitis from cyclophosphamide. Gastrointestinal effects such as nausea, vomiting, and diarrhea also are possible in any species treated.

In people, long-term therapy is discouraged because of the risk that cyclophosphamide will induce secondary malignancies. Secondary malignancies have not been reported in animals that have been treated.

Clinical Use

Compared to other immunosuppressive agents (azathioprine, cyclosporine, mycophenolate, leflunomide), cyclophosphamide has not been used regularly as an immunosuppressive drug in animals. The adverse effects at high doses can be severe, and efficacy has not been documented for diseases in animals (use has been anecdotal). Nevertheless, it is sometimes used as an alternative when other drugs have been ineffective. The dose administered to dogs is 50 mg/m^2, which is approximately 1.5 mg/kg for large dogs and 2.5 mg/kg for small dogs. It is available in 25 and 50-mg tablets. This dose has been administered EOD with corticosteroids administered on the alternate days. Cyclophosphamide also is administered at this dose by some clinicians as a pulse dose on 4 consecutive days/week (4 days on, 3 days off). Cats have received a total dose of 6.25–12.5 mg, once daily, 4 days per week.

For treatment of IMHA, the efficacy of cyclophosphamide has been questioned (Mason et al., 2003). In a study in which dogs were randomized to receive cyclophosphamide plus glucocorticoids or glucocorticoids alone, there was no added benefit from cyclophosphamide. Regeneration of red blood cells was suppressed in cyclophosphamide-treated animals.

Chlorambucil

Chlorambucil (Leukeran) also is a nitrogen mustard and is sometimes used as a substitute for cyclophosphamide. It has a similar action as cyclophosphamide, but is one of the slowest-acting of the class of nitrogen mustards. Although little has been published on the clinical use of chlorambucil, it may be effective in dogs and cats for immune-mediated disease. However, direct comparisons to other immunosuppressive drugs has not been reported. One of the most frequent uses has been for treatment of immune-mediated skin diseases of cats. In one report, cats with pemphigus and eosinophilic granuloma complex (EGC) responded favorably with few side effects (Helton-Rhodes and Shoulberg, 1992). It also has been used for feline pemphigus foliaceous at a dose of 0.17–0.38 mg/kg every other day (Irwin et al., 2012).

Adverse Effects

Chlorambucil lacks some of the adverse effects of cyclophosphamide. This drug has been administered for months to years to people safely. The bone-marrow suppressing effects are only moderate, compared to other nitrogen mustards, and are rapidly reversible. Chlorambucil has not caused cystitis, which is reported for cyclophosphamide.

Clinical Use

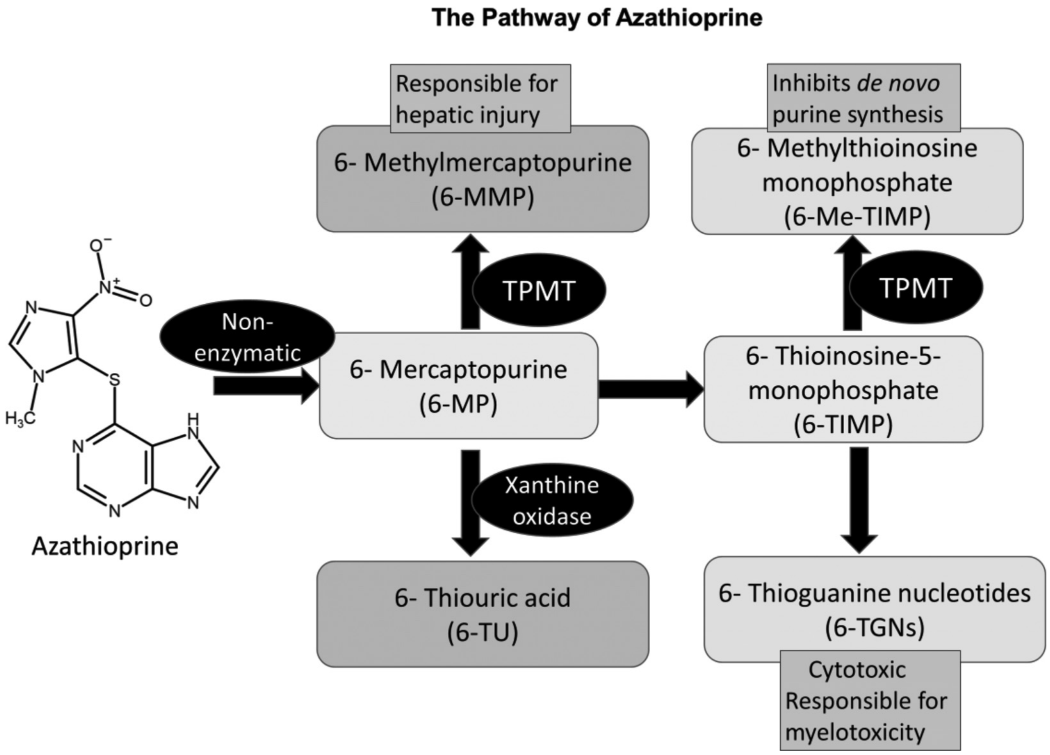
The usual dose in cats is 0.1–0.2 mg/kg, orally, q 24 h. The usual dose in dogs is 2–6 mg/m^2 q 24 h. After remission these doses are administered EOD. It is available as 2-mg tablets. The EOD dose may be given with oral prednisolone on alternate days.

Thiopurines (Azathioprine)

As first-line therapy, or as an alternative to nitrogen mustard alkylating agents for treatment of immune-mediated disease in dogs, thiopurines are often administered. The most common of the thiopurines used for this purpose is azathioprine (Imuran).

Mechanism of Action

Despite the widespread use of azathioprine, little is known in dogs about its metabolism, risk of adverse reactions, and mechanism of immune suppression (Rinkardt et al., 1999; Ogilvie et al., 1988). In people, azathioprine is rapidly and spontaneously metabolized to 6-mercaptopurine (6-MP), which is further metabolized to 6-methylmercaptopurine nucleotides (6-MMPN) and 6-thioguanine nucleotides (6-TGNs) (Figure 45.4). Conversion to metabolites may occur at target cells responsible for immune effects because direct administration of 6-MP is not as effective as administration of azathioprine as a prodrug. 6-TGNs are incorporated into DNA and are considered the active cytotoxic metabolites. These metabolites are responsible for the bone-marrow toxicity, cytotoxic effects, and immunosuppression of lymphocytes (Stefan et al., 2004; Lennard et al., 1989). 6-MMPNs, on the other hand, are inactive metabolites, but can produce some adverse effects, such as hepatic injury. An additional metabolite is the methylthioinosine monophosphate (MeTIMP), which has activity to inhibit de novo biosynthesis of purines in vitro, but the clinical significance is not known (Meggitt et al., 2011). Consequence of deficiencies of the enzyme thiopurine methyltransferase (TPMT) on clinical and toxic effects are discussed below.



The Pathway of Azathioprine
Azathioprine
Non-enzymatic
6- Mercaptopurine (6-MP)
TPMT
6- Methylmercaptopurine (6-MMP)
Responsible for hepatic injury
Xanthine oxidase
6- Thiouric acid (6-TU)
6- Thioinosine-5-monophosphate (6-TIMP)
TPMT
6- Methylthioinosine monophosphate (6-Me-TIMP)
Inhibits *de novo* purine synthesis
6- Thioguanine nucleotides (6-TGNs)
Cytotoxic Responsible for myelotoxicity

Figure 45.4 Metabolism of azathioprine. Azathioprine is quickly metabolized first to 6-mercaptopurine (6-MP) by a nonenzymatic reaction. 6-MP can then be metabolized to inactive metabolites 6-thiouric acid (6-TU) by xanthine oxidase, 6-methylmercaptopurine (6-MMP) by thiopurine methyltransferase (TPMT), or to active metabolites via 6-thioinosine-5-monophosphate (6-TIMP). Drugs that inhibit xanthine oxidase (e.g., allopurinol) can interfere with this pathway. The 6-thioguanine nucleotides (6-TGNs) can be incorporated into DNA and are thought to be the primary mechanism for the pharmacological effect as well as the myelotoxicity that can be seen in some individuals. The metabolite 6-methylthioinosine monophosphate (6-Me-TIMP) can inhibit the de novo synthesis of purines, but this may not be a significant clinical effect. Deficiencies in the enzyme TPMT in people and cats can lead to myelotoxicity, but this relationship has not been established for dogs.

Clinical Use

In veterinary medicine, azathioprine is one of the most commonly administered drugs to suppress immunity in dogs for treatment of dermatological disease, IMHA, intestinal disease, and other immune-mediated diseases (Grundy and Barton, 2001; Olivry et al., 2004; Hostutler et al., 2004; Weinkle et al., 2005). A systematic review of treatment of IMHA in dogs concluded that when a "second-line" agent was needed in addition to corticosteroids, azathioprine was associated with a more favorable outcome than other agents (Swann and Skelly, 2013). However, there are no good quality prospective studies available to assess the true benefit of adding azathioprine to corticosteroid therapy for these diseases.

Azathioprine is available as 50-mg tablets. It is dosed at 2 mg/kg, orally, q 24 h. Long-term therapy is administered at a dose of 0.5–1.0 mg/kg, every other day, with prednisolone administered on the alternate days. In cats, the doses are much lower, with 0.3 mg/kg being the safest (discussed in Section Problems in Cats). In people, there is a long lag period before successful treatment is recognized with azathioprine, which may be as long as 2–8 months. In veterinary medicine this lag period is probably shorter and therapeutic benefits have been observed after only 3–5 weeks, or less.

Adverse Effects

Azathioprine myelotoxicity has been well documented in dogs (Rinkardt and Kruth, 1996; Rodriguez et al., 2004). Leukopenia and thrombocytopenia can be serious. Animals that are treated with azathioprine should have the CBC monitored during therapy to identify the animals that may be at risk for toxicity and to adjust doses accordingly.

Gastrointestinal effects such as nausea and diarrhea may be only temporary and subside after several days of therapy. In people, elevated levels of 6-MMPNs are associated with hepatotoxicity (Stefan et al., 2004). Canine patients also have developed hepatic toxicity within 2–4 weeks after initiating azathioprine therapy. Signs of hepatopathy include liver enzyme increase and clinical signs that may result in discontinuation of treatment.

Long-term effects related to the immunosuppression produced by azathioprine include *Demodex* infection, recurrent pyoderma, and dermatophyte infections. Sterile hemorrhagic cystitis, the complication cited for cyclophosphamide, has not been seen with azathioprine. There has also been association (but not well documented) between the administration of azathioprine plus prednisolone and the development of acute pancreatitis in dogs. It has been suggested that this is caused by azathioprine's effect on decreasing pancreatic secretion in animals.

Problems in Cats

Some veterinarians have administered azathioprine to cats at a total dose of about 6.25 mg per cat (1/8 tablet) EOD. However, doses of 2.2 mg/kg EOD produced profound neutropenia in cats (Beale et al., 1992). Although doses of 1.1 mg/kg every day, or every other day, for treatment of pemphigus have been administered to cats (Caciolo et al., 1984), other references have discouraged its use in cats because of the bone-marrow suppressing effects, even at this dose (Helton-Rhodes, 1995). Differences in metabolism may explain the susceptibility in cats (discussed in Section Importance of Metabolic Pathway for Determining Toxicity). Because of the concern for toxicity, if azathioprine is used, a recommended dose is 0.3 mg/kg once daily to every other day.

Use in Horses

Based on occasional case reports, azathioprine has been used in horses when other treatments have failed (Divers, 2010). Clinical reports indicate that it is effective for immune-mediate diseases in horses, despite pharmacokinetic data that indicates that it is not well absorbed orally. It has been used for immune-mediated thrombocytopenia, IMHA, polysynovitis, and granulomatous enteritis. The dose used in horses is 3 mg/kg orally, q 24 h.

Importance of Metabolic Pathway for Determining Toxicity

Azathioprine toxicity may have a genetic component. After azathioprine is converted to 6-MP, it is further metabolized to other metabolites (Figure 45.4). One metabolic route is via xanthine oxidase to inactive metabolites. Allopurinol will decrease this route because it inhibits xanthine oxidase. Another metabolic route is via thiopurine methyltransferase (TPMT), which can convert 6-MP to hepatotoxic metabolites. The enzyme TPMT is also responsible for converting 6-thioinosine-5-monophosphate (6-TIMP) to other metabolites. In people there is genetic polymorphism that determines high or low levels of TPMT. People with low TPMT activity may have higher levels of 6-thioguanine nucleotides (6-TGNs) and are more responsive to therapy, but have a high incidence of toxicity (myelosuppression); people with high levels of TPMT activity have low incidence of toxicity but lower efficacy (Lennard et al., 1989). Most of the human population has high TPMT activity, but about 11% have low levels and are more prone to toxicity. In people with low TPMT activity, doses must be lowered.

In dogs, levels of TMPT also are highly variable. TPMT activity varied ninefold in a population of 177 dogs (Kidd et al., 2004). Another study with fewer dogs indicated 90% of dogs showing normal TPMT activity and 10% with low activity (White et al., 1998). The variation appears genetically determined, as it is in people. However, it is not clear whether low levels of TPMT in dogs represent a risk. In some dogs with a history of azathioprine-associated myelotoxicity the animals had either intermediate or high levels of TMPT (Rodriguez et al., 2004).

Cats, as suspected because of their susceptibility to toxicity, have low TPMT activity (Foster et al., 2000). Therefore, cats are sensitive to the toxicity of azathioprine. If azathioprine is used in cats, the dose should be much lower than in dogs.

Mycophenolate

Mycophenolate mofetil is an ester prodrug metabolized to the active compound mycophenolic acid (MPA). T and B lymphocytes are critically dependent on de novo synthesis of purine nucleotides. Mycophenolic acid is a potent inhibitor of inosine monophosphate dehydrogenate (IMPDH), an enzyme important for synthesis of purines in lymphocytes. There are two isoforms of this IMPDH, type I and type II. Type II is the form that is important in activated T- and B-cell lymphocytes and is more sensitive to the effects of mycophenolate. Therefore it suppresses lymphocyte proliferation and decreases antibody synthesis by B cells. It is available as a 250-mg capsule (CellCept). In people it is used as a replacement for azathioprine and has been primarily used for immune suppression in liver and kidney transplant patients. It is usually used in combination with glucocorticoids and/or cyclosporine.

Pharmacokinetics / Pharmacodynamics

At doses of 10, 20, and 30 mg/kg oral, to research dogs that underwent hematopoietic stem cell transplantation, the peak concentration (C_{MAX}) did not increase in proportion to the dose (at 20 mg/kg C_{MAX} was 16 μg/ml), and the authors noted that the doses had no linear association with the plasma mycophenolate concentration (Lange et al., 2008). The half-life was 2.9 hours at the low dose, but 4.6 hours at 30 mg/kg. This is shorter than in people and healthy dogs (Langman et al., 1996), and consequently the area-under-the-curve (AUC) is lower than comparable doses in people. The average half-life in healthy dogs (Langman et al., 1996) has been longer (8–9 hours) but with wide variation. In people, the AUC that corresponds to prevention of graft rejection is 30 μg ml/h, but in the dogs from the transplantation study (Lange et al., 2008) the highest dose (30 mg/kg) produced an AUC of only 21 μg/ml. The concentration needed for 50% inhibition of IMPDH in dogs is 200 μg/ml, but this is higher than in people (Langman et al., 1996). In canine studies, a dose of 20 mg/kg oral does not attain levels high enough to reach this target. Therefore, these doses produce exposures in dogs that may be less than the recommended targets for people.

Clinical Use

Mycophenolate has been used to treat immune-mediated diseases, including IMHA, aplastic anemia, immune-mediated thrombocytopenia, glomerulonephritis, myasthenia gravis, neurological disease, meningoencephalomyelitis, and immune-mediated skin diseases. Experience is mostly limited to some retrospective case reports in the veterinary literature. A common dose is 10–20 mg/kg twice daily, but more research is needed to define the optimum dosage. According to pharmacokinetic studies with mycophenolate in dogs, the short elimination rate may require frequent dosing to achieve successful results in some dogs (Langman et al., 1996). For treatment of pemphigus foliaceous it has been given at a dose of 22–39 mg/kg/day divided into three treatments. It was well-tolerated, but only three out of eight dogs who completed the study were improved (Byrne and Morris, 2001). When administered with corticosteroids for treatment of IMHA (10 mg/kg q 12 h) it was well tolerated, but produced no clinical benefits that were greater than corticosteroids plus other agents (Wang et al., 2013). Myasthenia gravis, which is a T-cell dependent and B-cell mediated process, has been treated with mycophenolate but the results in canine studies have been disappointing. At doses of 10–20 mg/kg there was no significant benefit and the authors concluded that the evidence did not support the use of mycophenolate for treatment of acquired myasthenia gravis in dogs (Dewey et al., 2010). It was reported to produce a partial or complete response in dogs for treatment of meningoencephalomyelitis when combined with corticosteroids, but it had to be discontinued in 20% of the dogs because of adverse gastrointestinal effects (Barnoon et al., 2016). Case reports consisting of small numbers of animals indicated that it may be beneficial for treating IMHA and ITP (West and Hart, 2014; Yau and Bianco, 2014). In a case report, 30 dogs treated with corticosteroids and mycophenolate for IMHA at an average dose of 20 mg/kg per day were compared to other combination protocols (glucocorticoids plus azathioprine, cyclosporine, or immunoglobulin (Wang et al., 2013). There was no difference between the mycophenolate-treated group and the other treatments, except that, at some points of evaluation, the mycophenolate group actually had worse outcomes. The experiences in cats have been limited, but there have been reports of use in cats to treat IMHA.

Adverse Effects

Dogs may be more prone to adverse gastrointestinal effects than other animals. The study cited earlier (Barnoon et al., 2016) reported a 20% incidence of adverse gastrointestinal problems that required discontinuation of treatment. In a case report of five dogs with IMHA treated with mycophenolate at 10–15 mg/kg every 8 hours, all dogs had gastrointestinal toxicity (West and Hart, 2014). The authors concluded that the treatment could not be justified for IMHA at the dose used in their study. The most common effects in dogs were nausea, vomiting, and diarrhea, which is related to a direct effect on the intestinal epithelium. These effects appear to increase at higher doses or more frequent dose intervals.

Leflunomide

Leflunomide (Arava) is an isoxazole immunosuppressive drug. Leflunomide is not active as the parent drug, but is converted to an active metabolite A77 1726 (also known as M1 or teriflunomide) that is responsible for clinical immunosuppressive effects. It inhibits the synthesis of pyrimidine via inhibition of the enzyme dihydro-orotate dehydrogenase. This enzyme is important for the de novo pyrimidine synthesis that is critical for function of activated and stimulated T and B lymphocytes. It also may produce antiinflammatory effects.

After oral absorption, the plasma concentrations of leflunomide are low and insignificant. But there are sufficient concentrations of the metabolite M1 that account for the immunosuppressive action. The metabolite M1 has a very long half-life in people (7–10 days) but is much shorter in dogs (21 hours) (Singer et al., 2011). In cats there was 100% oral absorption and the half-life was longer than in dogs (60 hours at 4 mg/kg oral) but not as long as in people (Mehl et al., 2012). Lymphocyte proliferation in cats at this dose was decreased by approximately 50%. In people, several days are required to accumulate to steady-state levels, and many months are needed for complete elimination after treatment is discontinued. In dogs, steady-state concentrations may be attained earlier, but the more rapid elimination in dogs raises questions about extrapolating dosage regimens from people to dogs. Effective doses for cats have not been established.

Indications and Clinical Uses

Leflunomide is used in people primarily for rheumatoid arthritis. In dogs it has been used for a variety of immune-mediated diseases as a substitute for other drugs such as azathioprine or mycophenolate. These diseases include myasthenia gravis, Evan's syndrome, IMHA, thrombocytopenia, and polymyositis/ polyarthritis (Gregory et al., 1998; Colopy et al., 2010). However, well-controlled clinical studies have not been performed to confirm efficacy and most of the use in veterinary medicine is based on anecdotal reports. Adverse effects in dogs may limit the clinical use (see Section Adverse Effects). Experience in cats is even more limited, except for pharmacokinetic studies and a case report on the use for rheumatoid arthritis (Mehl et al., 2012; Hanna, 2005).

Leflunomide is used most often in dogs for immunosuppressive treatment when other drugs have failed, or when the patient has become refractory to other drugs and a substitute is considered. In dogs it is administered orally, usually at 2 mg/kg every 12 hours, then tapered to 2 mg/kg once daily. For polyarthritis one report indicated that it was "safe and effective" at a dose of 3–4 mg/kg per day (Colopy et al., 2010). In cats, results of pharmacokinetic studies suggest an initial dose of 2 mg/kg for 2 days, followed by 2 mg/kg every other day (Mehl et al., 2012). In both dogs and cats, after an induction period, the dose may be decreased by 25% increments until the patient is stabilized or until the disease resolves.

Adverse Effects

The most common adverse effects in dogs have been decreased appetite and diarrhea. Mild anemia and lethargy also have been observed with clinical use. The most detailed report on adverse effects was in the study by McChesney et al. (1994). They used a canine model for renal transplantation and administered leflunomide to dogs at doses of 2, 4, 8, and 16 mg/kg per day. At the low doses, up to 8 mg/kg, it was safe, but did not produce sufficient immunosuppression and all dogs rejected their grafts. As the dose was increased, the dogs became progressively anorexic. At a dose high enough to produce sufficient immunosuppression (16 mg/kg per day) there was severe toxicity with all dogs dying of anemia, anorexia, and weight loss. The dog may be sensitive to adverse effects because at the high dose of 16 mg/kg, the blood concentrations achieved were >50 μg/ml, which are levels that have been well tolerated in human studies.

Gold Therapy (Chrysotherapy)

Derivatives of gold salts such as aurothioglucose (Solganal) have been used to treat some immune-mediated diseases, but its use in veterinary medicine has diminished considerably. In people, its most common use was for rheumatoid arthritis but newer agents have largely replaced gold therapy. It was originally used in the 1800s to treat tuberculosis. The exact mechanism of action is unknown but it may exert the immunomodulating through its effects on T-lymphocyte cell-mediated immunity or via inhibition of sulfhydral enzyme systems (Kean et al., 1997). There also may be an antiinflammatory effect on macrophages and neutrophils. A disadvantage of gold therapy is that the most effective treatment must be it must be administered IM (usually once per week) and it may take several weeks for positive effects to occur. For example, in people, aurothioglucose has an onset of action of 6–8 weeks; in dogs this may be as long as 6–12 weeks.

Available Drugs

Gold therapy – referred to as chrysotherapy in some textbooks – includes various formulations of gold. Older formulations no longer exist commercially. Previously available formulations included gold sodium thiomalate (Myochrysine) as a 25 or 50 mg/ml injection in sesame oil and aurothioglucose (Solganal) as a 50 mg/ml injection in an aqueous formulation. The only formulation used currently for gold therapy is the oral monomeric gold formulation, auranofin (Ridaura) (Kean al., 1997), which is available in 3-mg capsules.

Clinical Use

Controlled studies are not available in veterinary medicine and case reports of successful therapy in the veterinary literature are lacking. The most common use (although rare) has been treatment of immune-mediated dermatological disease unresponsive to corticosteroids alone, or in cases in which one wishes to decrease the patient's reliance on corticosteroids. More recently, it has gained renewed interest in human medicine for its antiprotozoal properties (Madeira et al., 2012). Oral auranofin appears to concentrate in intestinal cells and may be effective for intestinal diseases caused by protozoa. This use has not been reported in veterinary medicine.

Doses

The injectable dose is usually administered as a 1 mg test dose in small dogs or 5 mg to larger canine patients. Doses have been administered once per week until remission, and usually maintenance doses are in the range of 1–2 mg/kg every 2–4 weeks. Doses for the oral drug auranofin have not been established for dogs or cats.

Adverse Effects

The adverse effects are described in people, in which there is a 10–50% incidence, but they are not well documented in animals. Reported adverse effects include dermatitis (which could be confused with the underlying problem being treated), nephrotoxicity, and blood dyscrasias. When administered to animals it is recommended to monitor CBC periodically to detect drug-induced problems. Diarrhea has been reported with the oral product. In pregnant animals these drugs should not be used. They cause abortion and fetal resorption or congenital malformations in laboratory animals.

Dapsone

Dapsone is a sulfone, which shares chemical properties with sulfonamides. It has been in use for over 50 years in human medicine, but use has declined significantly in favor of other agents. It has been used in combination with other drugs to treat leprosy in humans caused by *Mycobacterium leprae*. Other uses include prophylaxis for malaria and treatment of *Pneumocystis carinii* infections in AIDS patients. The dermatological uses include treatment of dermatitis herpetiformis, SLE, pemphigoid, subcorneal pustular dermatosis, and other inflammatory dermatoses.

Mechanism of Action

For treating leprosy, dapsone acts as a folate antagonist, similar to sulfonamides. For other conditions, the mechanism is unknown, but its action appears to be attributed to a suppression of neutrophil function (Booth et al., 1992). It may suppress respiratory burst in inflammatory cells.

Pharmacokinetics

Similarities in metabolism to the sulfonamides are expected. It is highly absorbed with a long elimination half-life of 11–13 hours in experimental dogs. Comparison of metabolic pathway between dogs and people and between cats and people may explain susceptibility to toxicity (see Section Adverse Effects). In people, one pathway for metabolism is acetylation (N-acetylation). The other metabolite in people is a hydroxylamine metabolite (N-hydroxylation). This hydroxylamine metabolite is responsible for adverse effects caused by dapsone, such as methemoglobinemia (Helton-Rhodes and Shoulberg, 1992). Dogs cannot acetylate drugs and a pattern of metabolism of sulfonamides has been identified in dogs that indicates that this lack of acetylation may account for a greater accumulation of toxic metabolites and increased risk of adverse effects (see discussion of sulfonamides in Chapter 32). The same metabolic fate may explain the risk of adverse effects from dapsone in dogs.

Clinical Use in Animals

In animals, dapsone has been used for feline leprosy, although efficacy for this disease is uncertain. In dogs, it has been used for dermatological conditions characterized by vascular disorders, inflammatory skin disease, immune-mediated disease, and subcorneal pustular dermatosis. Since specific studies have not been performed, doses are extrapolated from humans or based on empiricism. Doses listed in textbooks are in the range of 1 mg/kg once, twice, or three times daily. It is available in 25 and 100-mg generic tablets.

Adverse Effects

The adverse effects in animals are not well documented, but can be severe enough to discontinue therapy. In people, dapsone causes agranulocytosis, aplastic anemia, methemoglobinemia, and blood dyscrasias. Toxic dermatological reactions (e.g., toxic epidermal necrolysis) may occur. Because of the similarity to sulfonamides, do not administer to animals sensitive to sulfonamides. Since some dogs may have an inability to detoxify the hydroxylamine metabolite, this could possibly lead to a higher risk of toxicity. Cats are reported to be susceptible to hepatitis and blood dyscrasias. In people, one of the metabolites responsible for toxicity is excreted as a glucuronide metabolite. Cats may be unable to rapidly glucuronate this metabolite, which may increase a cat's risk of toxicosis compared to other animals.

Drugs for Treating Gastrointestinal Diseases

Mark G. Papich

Antiemetic Drugs

Neurotransmitters Involved in Vomiting

Several neurotransmitters are important for stimulating vomiting (Table 46.1) and successful therapy involves blocking one or more of the receptors for these neurotransmitters. There are differences between dogs and cats with respect to the importance of various receptors, and there are also differences between dogs, cats, and people. Dogs respond readily to administration of apomorphine, which is an agonist for dopamine. Cats vomit more readily from stimulation of α_2-adrenergic receptors than dogs, and respond more consistently to administration of the α_2-adrenergic agonists xylazine or dexmedetomidine. Histamine seems to be a more important neurotransmitter in the chemoreceptor trigger zone (CRTZ) in people than dogs or cats. These differences and overlapping effects of neurotransmitters can be confusing, but some generalities can be made, as follows.

- In the emetic (vomiting), histamine (H_1), acetylcholine (muscarinic M_1), serotonin (5-HT_3), dopamine (DA_2), and neurokinin (NK-1) all play some role, although the importance may vary among species.
- In the CRTZ, dopamine, serotonin, and acetylcholine (muscarinic) all play a role. Histamine has uncertain importance in dogs and cats. Drugs that block dopamine can be effective antiemetics from stimulation of the CRTZ in most animals.
- In the vestibular apparatus (motion sickness) acetylcholine (muscarinic receptor) and histamine (H_1) are important. Serotonin and adrenergic receptors also may play a role. Anticholinergic drugs (e.g., scopolamine) and antihistaminic drugs (e.g., diphenhydramine) can produce an antimotion sickness, antiemetic effect in people, but are less effective in dogs. Some of this may be caused by pharmacokinetic differences.
- Afferents from the gastrointestinal (GI) system may mediate vomiting. Cancer drugs (e.g., cisplatin) injure the GI tract and release serotonin (5-HT_3). Cancer drugs also may stimulate the CRTZ directly.
- Neurokinin (substance P, NK-1) is a more recently described neurotransmitter that stimulates vomiting from several sources. NK-1 receptors are found in the emetic center and the CRTZ, but the most important are those receptors in the emetic center. Drugs described as NK-1 receptor blockers (e.g., maropitant, aprepitant) block vomiting from several sources, but seem to be less effective for alleviating nausea.

Phenothiazine Tranquilizers

Dopamine is one of the neurotransmitters in the emetic center and CRTZ for stimulating vomiting at the DA_2 receptor. Phenothiazine tranquilizers such as chlorpromazine (Thorazine®), prochlorperazine (Compazine®), promethazine, and acepromazine antagonize stimulation from dopamine in the CNS (Table 46.2). In addition to the antidopamine effects, these drugs can block alpha-adrenergic receptors (α_1) in the emetic center. Some phenothiazines also block the histaminic and muscarinic (M_1) receptors. Because of this broad action, and ability to inhibit vomiting from a variety of stimuli, this group of drugs has been called “broad-spectrum” antiemetics. Their side effects may limit clinical use in some patients. These side effects include sedation, altered involuntary motor activity (extrapyramidal signs), and peripheral α-adrenergic receptor blockade (vasodilation). Metoclopramide (discussed in section Metoclopramide (Reglan®)) also has antiemetic effects through its action on the DA_2 receptor.

Antimuscarinic Drugs

Drugs that block muscarinic receptors (muscarinic M_1 receptor) include atropine, scopolamine, aminopentamide (Centrine®), and isopropamide (isopropamide is combined with prochlorperazine in Darbazine®) (Table 46.2). These drugs decrease vomiting from various

Table 46.1 Neurotransmitters important in vomiting

Dopamine, type 2 (DA_2)
Histamine (H_1)
Serotonin type 3 ($5\text{-}HT_3$)
Acetylcholine, muscarinic type 1 (M_1)
Substance P, neurokinin (NK-1)

Table 46.2 Antiemetic drugs and doses

Antihistamines	
diphenhydramine (Benadryl®)	2–4 mg/kg, IM, PO, q8–12h
dimenhydrinate (Dramamine®)	4–8 mg/kg, PO, q8–12h
promethazine (Phenergan®)	0.2–0.4 mg/kg, PO, IM, q8h
Phenothiazines	
chlorpromazine (Thorazine®)	0.5 mg/kg, IM, PO, q6–8h
prochlorperazine (Compazine®)	0.1–0.5 mg/kg, IM, q6–8h
Acepromazine	0.1 mg/kg, IM, PO, q12h
triflupromazine (Vesprin®)	0.1–0.3 mg/kg, IM, PO, q8–12h
trifluperazine (Stelazine®)	0.03 mg/kg, IM, q12h
triethylperazine (Torecan®)	0.13–0.2 mg/kg, IM, q8–12h
metoclopramide (Reglan®)	0.1–0.3 mg/kg, IM, PO, q12h
Anticholinergic drugs	
Atropine	0.02–0.04 mg/kg, IM, SC, q8–12h
methscopolamine (Pamine®)	0.3–1.0 mg/kg, PO, q8h
isopropamide (Darbid®)	0.2–1.0 mg/kg, PO, q12h
Antiserotonin drugs	
ondansetron (Zofran®)	0.5–1.0 mg/kg, IV or oral 30 min prior to administration of cancer drugs For vomiting from other causes, 0.1–0.2 mg/kg slow IV injection and repeated every 6–12h to control vomiting
NK-1 Receptor blockers	
Aprepitant (Emend®, human drug)	1 mg/kg PO, q24h.
Maropitant (Cerenia®)	1 mg/kg SC, q24h, 2 mg/kg oral q24h, or 8 mg/kg oral (for prevention of motion sickness)

causes, including vomiting caused by vestibular stimulation (motion sickness) and stimulation of the CRTZ. In people, scopolamine has been one of the most effective agents for treating motion sickness (Transderm-Scop®), but it is less effective in dogs and cats. The adverse effects of anticholinergic drugs include xerostomia, decreased stomach emptying, ileus, urine retention, and constipation. These drugs are not practical for many of the causes of vomiting that are encountered in veterinary medicine. The adverse effects, including potential for ileus, can lead to other complications. These agents should be used cautiously in patients with glaucoma because there is a risk of increased intraocular pressure. Scopolamine has produced excitement in animals, particularly cats.

Antihistaminic Drugs

The histamine H_1 and H_2 receptor is involved in transmission of vomiting. Antihistamine drugs are discussed further in Chapter 19. Histaminic nerve transmission stimulates vomiting from the CRTZ and vestibular apparatus. This pathway does not appear to be important for cats, and is less important in dogs than in people. Antihistamines also can produce antimuscarinic (atropine-like) effects as well. Some of the phenothiazine drugs also act on histamine receptors and there is some crossover between these drug groups. Antihistamine drugs administered to control vomiting have included diphenhydramine (Benadryl®), dimenhydrinate (Dramamine®), promethazine (Phenergan®, a phenothiazine with antihistamine effects), and cyclizine, (Marezine®) (Table 46.2). Dimenhydrinate and diphenhydramine contain the same drug. Dimenhydrinate contains 54% diphenhydramine and 46% 8-chlorotheophylline. Theophylline is added to the human formulation to decrease the drowsiness from the antihistamine component. In dogs there was greater oral absorption of diphenhydramine when administered as dimenhydrinate than from diphenhydramine alone.

There are few published data on pharmacokinetics of antihistamine drugs in dogs or cats. Diphenhydramine oral absorption was only 8% in dogs and was highly variable. Oral absorption was better when administered as dimenhydrinate (23%) and had a half-life of 11.6 hours, but was highly variable. The half-life of diphenhydramine injection is only 2 hours in dogs. For other antihistamines, the perceived lack of efficacy of antihistamines that has been reported may be caused by poor oral bioavailability, rather than lack of effect at the receptor.

Adverse Effects

The antihistamines are relatively safe drugs. The most significant side effect of therapy is sedation, but this usually is not undesirable in most patients being treated for vomiting. Sedation occurs because the H_1 receptor regulates sleep–wake cycles. The ethanolamines (diphenhydramine and dimenhydrinate) have the greatest sedative effects. Paradoxically, some of the antihistamines have caused excitement in cats.

Metoclopramide (Reglan®)

Metoclopramide has antiemetic effects via three mechanisms: (i) metoclopramide (at low doses) inhibits dopaminergic (DA_2) transmission in the CNS, similar to phenothiazines; (ii) metoclopramide has peripheral effects on the GI tract that increase emptying of the stomach and upper duodenum; (iii) metoclopramide (at high doses) inhibits serotonin (5-HT_3) receptors. 5-HT_3 stimulates vomiting in dogs and cats either in the CRTZ or vagal afferent neurons. Metoclopramide is a broad-spectrum antiemetic that has been popular in small animal medicine, particularly for animals that vomit because of drug therapy (e.g., cancer drugs) or gastrointestinal disease. However, for control of vomiting caused by cancer drugs the results have often been disappointing (Fukui et al., 1992). This drug is also discussed later in the section on prokinetic agents.

Pharmacokinetics

There is large variability in the pharmacokinetics of metoclopramide in dogs. The half-life in dogs has ranged from about 100 to 190 minutes; the systemic availability of an oral dose is only about 50%. The dose administered to dogs and cats is based in extrapolation and empirical use rather than pharmacokinetic studies.

Adverse Effects

Metoclopramide is a dopamine antagonist and at high dosages it can produce adverse reactions that are similar to those caused by phenothiazine drugs. Adverse CNS effects from metoclopramide include excitement and behavior changes. To produce adequate antiemetic effects from blocking 5-HT receptors, high doses may be needed, which increase the risk of extrapyramidal CNS effects attributed to central dopamine (DA_2) antagonism.

The increase in GI motility may produce some abdominal discomfort. Because metoclopramide stimulates upper GI motility, it should not be administered if there is an obstruction. Metoclopramide produces transient endocrine changes, including an increase in prolactin, but the significance of this effect in dogs and cats has not been determined.

Serotonin Antagonists

The pharmacology of serotonin and the antagonists are covered in more detail in Chapter 19. Specific serotonin antagonists include ondansetron (Zofran), granisetron (Kytril), palonosetron (Aloxi), and dolasetron (Anzemet). New drugs in development include tropisetron and azasetron. Of these, ondansetron (Zofran®) is the best known to veterinarians of the specific serotonin (5-HT_3) inhibitors.

Ondansetron has been used to treat vomiting associated with cancer chemotherapy as well as nausea and vomiting caused by gastroenteritis, pancreatitis, and inflammatory bowel disease. In cats, the oral absorption was 32% from oral administration and 75% from subcutaneous administration. The half-life in cats was 1.8 hours from IV administration, 1.2 hours from oral administration, and more prolonged (3.2 hours) from subcutaneous administration. In dogs, it is much less bioavailable (<10%) after oral administration and shorter half-life of 30 minutes, raising questions about the clinical effectiveness of ondansetron in dogs.

The doses used for ondansetron are 0.5–1.0 mg/kg, IV or oral 30 minutes prior to administration of cancer drugs. For other diseases it has been administered at a dose of 0.1–0.2 mg/kg to dogs and cats and increased to 0.5 mg/kg if necessary, and given as often as every 12 hours. Because of concerns regarding oral absorption in dogs to obtain full effects, it should be administered intravenously. Other serotonin antagonists used for antiemetic therapy include granisetron, ondansetron, dolasetron, azasetron, and tropisetron.

As discussed in Section Metoclopramide (Reglan®), metoclopramide at high doses of 1–3 mg/kg can act as a serotonin antagonist and have been used as an IV infusion during cancer chemotherapy to decrease vomiting; but adverse effects are more likely at these high doses.

Glucocorticoids

Glucocorticoids such as dexamethasone have antiemetic properties, possibly by inhibiting prostaglandin synthesis. These drugs are used sometimes in addition to other drugs for decreasing vomiting, particularly when it is caused by cancer chemotherapy. Glucocorticoids are covered in more detail in Chapter 29.

Cannabinoids

Cannabinoids have been used in people who have not responded to any other antiemetic drugs (e.g., patients that are receiving anticancer drugs). The availability of medical marijuana and prescription forms of cannabinoids have increase the interest in the use in veterinary medicine. They have also been used to increase the appetite in human patients with terminal disease, cancer, and AIDS. Except for anecdotal accounts, the use has not been reported in veterinary patients. These agents have been used occasionally by some veterinarians to increase the appetite in cats, but these effects have been untested in clinical studies.

There are approximately 100 cannabinoids in the cannabis plant, but delta-9 tetrahydrocannabinol (Δ^9-THC) is believed to be the most pharmacologically active. There are two important cannabinoid receptors: CB1 and CB2. The CB2 receptor is almost entirely peripheral and responsible for antiinflammatory and antinociceptive effects. The CB1 receptor is located centrally and is responsible for antinausea, psychoactive effects, appetite stimulation, and other central nervous system properties (Vemuri and Makriyannis, 2015). The effect on nausea and vomiting may occur from binding to the CB1 cannabinoid receptor in the emetic center.

The active ingredient in many cannabinoid products is Δ^9-THC. Δ^{9-}THC is a partial agonist for CB1 and CB2. Synthetic marijuana (THC) is available as a prescription drug (dronabinol) for antiemetic therapy; it is marketed as Marinol®. Cannabinoids are relatively well tolerated in people, but side effects include drowsiness, dizziness, ataxia, and disorientation. Withdrawal signs may occur after abrupt discontinuation following repeated doses. For dronabinol, the oral absorption is good, but bioavailability is low due to high first-pass effects. The volume of distribution is very high.

Suggested doses for dronabinol (Marinol®) in animals (but untested in clinical trials) are 5 mg/m^2, and increased as needed up to 15 mg/m^2 for antiemetic administration prior to chemotherapy. For appetite stimulation in animals, doses start at 2.5 mg before meals. It is available as 2.5, 5, and 10-mg capsules.

NK-1 Receptor Antagonists

The neurotransmitter neurokinin-1 (NK-1, also known as substance P) has several functions that include regulating vascular tone and permeability, mucus production and bronchial tone in the respiratory tract, heart rate, and some activity in the central nervous system. The effects on the emetic center led to the development of a new class of antiemetics to antagonize this receptor. The first one approved for use in people for cancer chemotherapy-induced vomiting was aprepitant (Emend®), which was the first substance P/neurokinin-1 (NK-1) receptor antagonist (Dando and Perry, 2004). The use of NK-1 receptor antagonists such as aprepitant in dogs was primarily experimental until the approval of a specific veterinary drug, maropitant citrate (Cerenia®) (Wu et al., 2004; Watson et al., 1995; Huskey et al., 2004; Fukuda et al., 1999; de la Puente-Redondo et al., 2007a; Vail et al., 2007). This agent was approved for use in dogs in 2007, and later approved for cats in 2012. It is available as a 10 mg/ml injection to be administered 1 mg/kg once daily SC for up to 5 days, or a tablet 16, 24, 60, or 160 mg to be administered at a dose of 2 mg/kg per day, PO, for up to 5 days. The tablet can also be used to prevent vomiting caused by motion sickness (vestibulitis) at a dose of 8 mg/kg for up to 2 days. The dosing interval can also be extended to 14 days without significant accumulation as described below in Section Pharmacokinetic. The original approval for dogs and cats restricted injection of maropitant to the SC route. However, some patients may have a painful reaction to SC injection (discussed in Section Adverse Effects). Subsequently, the sponsor obtained FDA approval for intravenous route of administration in dogs and cats to prevent vomiting associated with anesthesia and medical procedures.

The efficacy of maropitant is attributed to its central site of action. It blocks neurokinin-1 (NK-1) receptors in the area of the brain called the *nucleus tractus solitarius* – the site known as the *emetic center*. Input into the emetic center may come from different sources: gastrointestinal tract, higher brain centers, CRTZ, and vestibular apparatus (motion sickness). These inputs also utilize a variety of neurotransmitters: dopamine, histamine, acetylcholine, and serotonin. Traditionally, to block emesis from these stimuli, multiple drugs may be needed: antihistamines, antidopamine drugs (e.g., metoclopramide), dopamine antagonists (e.g., phenothiazines), and serotonin antagonists (e.g., ondansetron). Because NK-1 inhibitors – such as maropitant – block input from multiple sources regardless of the input *they are considered broad spectrum* in action.

Pharmacokinetics

Maropitant is extensively metabolized by the liver and there is little clearance by the kidney; therefore, no dose adjustments are needed in patients with compromised kidney function. There are primarily two canine isoforms involved with metabolism: CYP2D15 and CYP3A1 (Benchaoui et al., 2007a). Absorption from SC administration is rapid and complete (91% absorption), but oral absorption is limited by the first-pass metabolic effects (24% at 2 mg/kg and 37% at 8 mg/kg) (Benchaoui et al., 2007a). The half-life is 7.75 hours and 4–5.5 hours after SC and oral administration, respectively. However, the effects persist for at least 24 hours after a dose, presumably because of binding to the CNS NK-1 receptor that maintains the drug at the site of action. Penetration across the blood–brain barrier has been demonstrated (de la Puente-Redondo, 2007c), which is necessary for activity in the emetic center.

After repeated administration for 14 days, the half-life was 9.22 hours (mean) and 22 hours after doses of 2 mg/kg and 8 mg/kg, respectively (Lesman et al., 2013). In early label warnings there was a concern about accumulation of maropitant after administration consecutively for more than 5 days. However, follow-up pharmacokinetic studies examined administration of maropitant to dogs at a dose of 2 and 8 mg/kg for 14 consecutive days and steady state was achieved after four doses for once-daily 2 mg/kg and after eight doses for daily 8 mg/kg administration. The explanation for this lack of significant accumulation caused by saturation is that even though saturation of the CYP2D15 occurs at the label dosages causing nonlinear pharmacokinetics, at higher concentrations, the CYP3A12 becomes the primary metabolizing enzyme and linear pharmacokinetics are re-established (Lesman et al., 2013). Therefore, there was not significant accumulation used at the low dose of 2 mg/kg or the high dose of 8 mg/kg for 14 days.

Maropitant in Dogs

Maropitant is an effective antiemetic for a variety of stimuli, including cisplatin (chemotherapy)-induced vomiting, pancreatitis, enteritis, copper sulfate and apomorphine-induced vomiting, motion sickness, and ipecac-induced vomiting. In clinical and research trials, maropitant has been effective to treat and prevent chemotherapy-induced vomiting in dogs (Vail et al., 2007; de la Puente-Redondo, 2007a; Benchaoui et al., 2007b) and a wide range of stimuli such as viral disease, food and toxin ingestion, enteropathy, and other diseases (de la Puente-Redondo et al., 2007b). It was more effective than metoclopramide in this trial.

Maropitant has been effective in dogs that were prone to vomiting because of opiate premedication (Lorenzutti et al., 2016; Kraus, 2013, 2014a; Koh et al., 2014; Claude et al., 2014). In these trials, it inhibited vomiting caused by morphine and hydromorphone. The dose in these studies (1 mg/kg, SC or 2 mg/kg oral) was more effective if administered prior to the anesthesia medication (30–60 minutes for injection or 2 hours for oral). In some of the studies in dogs (Kraus, 2014b; Lorenzutti et al., 2016; Benchaoui et al., 2007a) maropitant was effective for reducing vomiting, but less effective for relieving nausea. This observation may indicate that maropitant is highly effective at the vomiting center to decrease emesis, but less effective for preventing the feelings of nausea.

Maropitant in Cats

Maropitant (Cerenia) was approved by the FDA for use in cats in 2012. The antiemetic effects have been demonstrated in both clinical and research cats (Hickman et al., 2009). Oral absorption is higher than dogs (50%) and the long half-life in cats (13–17 hours) is suitable for once-daily administration. It has been tolerated at doses of 0.5–5 mg/kg SC every day for 15 doses. The recommended dose for cats is 1 mg/kg for vomiting caused by motion sickness, and other causes that stimulate the vomiting center.

In addition to the uses listed above, maropitant was effective for reducing the incidence of vomiting associated with dexmedetomidine and morphine (Martin-Flores et al., 2016). However, as observed in the canine studies described above, it was more effective for reducing vomiting than for reducing nausea. In a study in cats with chronic kidney disease, maropitant prevented vomiting in these cats, but did not improve appetite or weight gain (Quimby et al., 2015). Therefore, as observed in some studies with dogs, maropitant may be effective for preventing vomiting, but may not prevent nausea to a similar degree.

Adverse Effects

Compared to other antiemetic drugs, maropitant has had a good safety profile. There are NK-1, -2, and -3 receptors throughout the body. Maropitant has little binding affinity to NK receptors, other than NK-1; it also does not bind to other CNS receptors such as GABA, opiate, adrenergic, serotonin, histamine, muscarinic, or dopamine receptors. Although NK-1 receptors are involved in a large number of other physiological and behavioral responses, at doses used for antiemesis in dogs, there were no adverse effects associated with these other functions.

One of the adverse effects reported is pain or a stinging response when injected subcutaneously (SC). This is caused by the irritant effect of the drug formulation when it dissociates at room temperature (Narishetty et al., 2009). Maropitant forms a molecular inclusion complex with a clodextrin in the formulation but, at refrigerated temperatures, the drug remains complexed within the cyclodextrin cavity. This complex provides higher drug solubility and improved injection-site tolerance. Entrapment of drugs in this cyclodextrin cavity prevents the direct contact of the drug with biological membranes by limiting the free drug concentration and thus reduces the injection related local irritation. This drug complex will remain intact and is less likely to cause pain from injection if refrigerated between uses.

Other Uses

Because NK-1 is also involved in transmission of pain, there has been interest in using these antagonists for analgesia. In dogs, administration of maropitant (1 mg/kg IV, followed by continuous intravenous infusion, CRI) has decreased anesthetic requirements in dogs undergoing abdominal surgery (Boscan et al., 2011). Maropitant was shown in an uncontrolled study to decreasing coughing in dogs with chronic bronchitis. Although it decreased the severity and frequency of coughing, it had no effect on airway inflammation (Grobman and Reinero, 2016). It is presumed that the antitussive effect is through a central effect on NK-1 receptors in the cough center.

Mirtazapine (Remeron)

Mirtazapine is used more often as an appetite stimulant – especially in cats – but it also has antiemetic properties and is briefly discussed here and also included in Chapter 18, along with other appetite-stimulating drugs for cats. Mirtazapine is used as an antidepressant medication in people and is used to treat mood disorders. Its mechanism of action is unknown but it may enhance central noradrenergic and serotonergic activity. In animals it has appetite-stimulating and antinausea properties. These effects are attributed to the 5-HT_3 antagonist properties; therefore, it may share similar effects as antiserotonin medications discussed in Section Serotonin Antagonists.

Clinical Use

Mirtazapine has been studied more in cats than in dogs (Quimby and Lunn, 2013). These studies in cats demonstrated that it is an effective appetite stimulant. The dose is usually 1.88 mg per cat oral. At high doses it produces adverse effects that include vocalization and increased restlessness. In cats it has a half-life of approximately 10 hours, which allows for once-daily dosing. In cats with chronic kidney disease – for which appetite stimulation often is desired – clearance is slower and the half-life increases to 15 hours, which indicates that an every-other-day dosing schedule should be used in cats with kidney disease to avoid accumulation (Quimby et al., 2011). Mirtazapine is available as 7.5-mg tablets, but also is available in 15, 30, and 45-mg sizes. The formulation that some veterinarians prefer is a rapidly disintegrating oral tablet that dissolves easily in an animal's mouth (15, 30, and 45 mg).

Gastrointestinal Prokinetic Drugs

Prokinetic drugs increase gastrointestinal motility (Washabau and Hall, 1997). They are used in dogs, cats, horses, and occasionally ruminants to stimulate gastric emptying, rumen motility, or to increase intestinal motility (Whitehead et al., 2016). Intestinal motility is sometimes decreased after intestinal disease or surgery and can lead to ileus. Some of these drugs are intended to restore normal motility to facilitate recovery.

Metoclopramide (Reglan®, Maxeran®)

Metoclopramide has multiple actions. It is a dopamine (DA_2) antagonist, serotonin (5-HT_4) agonist and serotonin (5-HT_3) antagonist. Among the proposed mechanisms of metoclopramide is an increase in the release of acetylcholine in the GI tract, possibly via a prejunctional mechanism. It also may increase motility of gastric smooth muscle by increasing sensitivity of the cholinergic response. Since it also is a dopamine antagonist, it may antagonize dopamine's (DA_2) inhibitory action on GI motility.

Metoclopramide increases gastric emptying, increases the tone of the esophageal sphincter, and stimulates motility of the duodenum. It has less effect on distal segments of the intestine. Metoclopramide acts centrally to inhibit DA_2, which produces the antiemetic effects discussed in Section Antiemetic Drugs. In people, metoclopramide also has been used to treat hiccups and lactation deficiency.

Adverse effects from metoclopramide can include excitement (seen in horses, for example), anxiety, and involuntary muscle movements. There are also endocrine effects: There is a transient increase in prolactin and aldosterone. *Since some breast cancers are prolactin-dependent, there has been some concern about the carcinogenicity of this drug in women.*

Use in Small Animals

In dogs metoclopramide has been used as an antiemetic more commonly than other drugs. Although it has been used to promote GI motility as well, this effect is less established than previously thought (Whitehead et al., 2016). For example, it is of little benefit to increase stomach emptying in disorders of gastroparesis or chronic regurgitation. It also has been used to stimulate normal upper motility following surgery (e.g., corrective surgery for gastric dilatation), but one study showed that metoclopramide did *not* change gastric motor activity to promote gastric emptying in dogs with gastric dilatation volvulus (Hall et al., 1996). In another study, it reduced, but did not prevent gastroesophageal reflux in anesthetized dogs at a dose of 1 mg/kg (Wilson et al., 2006). Doses are in the range of 0.25 to 0.5 mg/kg, q 8–12 h, but they have been increased to 1–2 mg/kg.

Use in Horses

Some equine surgeons have used infusions of metoclopramide (0.125–0.25 mg/kg/h) added to IV fluids to reduce postoperative ileus in horses (Gerring and Hunt, 1986). It may stimulate small intestine – but not large bowel – motility, but this has little benefit for horses with intestinal ileus (Sojka et al., 1988). Undesirable side effects in horses have been common, and include behavioral changes and abdominal pain. Since this drug transiently increases prolactin secretion, there has been interest in using this drug for treating agalactia in animals, but efficacy has not been determined. Domperidone is preferred for this effect (see Section Domperidone (Motilium, Equidone)).

Use in Ruminants

The clinical use of metoclopramide in large animals has not been as common as in small animals. Metoclopramide has little usefulness in cattle, although it may increase the motility of the rumen in cattle and sheep. It has been used successfully in some cattle with functional pyloric stenosis (Braun et al., 1990), but was not effective in calves (0.1 mg/kg IM). At doses higher than 0.1 mg/kg in calves it caused severe neurological side effects (Wittek and Constable, 2005).

Domperidone (Motilium, Equidone)

Domperidone is a dopamine-2 receptor (DA_2) antagonist. It may also have α_1-receptor antagonist and serotonin ($5\text{-}HT_2$) antagonist effects. It has been available as a 10-mg tablet outside the USA as a human prokinetic drug but not allowed for human use in the USA because of cardiac toxicity. Its mechanism of action and GI prokinetic effects are similar to metoclopramide, but its efficacy has not been very impressive in animals and thus a clinical use has not been recommended (Whitehead et al., 2016). A difference between metoclopramide and domperidone is that the latter does not cross the blood–brain barrier. Therefore, adverse CNS effects are not as much of a problem compared to metoclopramide in horses. It may have antiemetic properties, but only if the stimulus for vomiting affects the CRTZ. It is capable of reaching the area postrema of the brain because this area is not protected by the blood–brain barrier. An additional effect is to stimulate lactation (see Section Use in Horses).

Use in Small Animals

The use is not reported, but it will produce a prokinetic effect in dogs at a dose of 0.05–0.1 mg/kg (2–5 mg/animal).

Use in Horses

Domperidone has been investigated for use in horses to treat fescue toxicity and agalactia. Fescue toxicosis is caused by a fungus that produces a toxin that induces reproductive toxicity in horses. The action of domperidone to increase lactation is through the stimulation of prolactin. It is approved by the FDA as an equine formulation of domperidone (Equidone oral gel, 11%). The approved dose is 1.1 mg/kg once daily starting 10–15 days prior to the anticipated foaling date. Treatment may be continued for up to 5 days after foaling if mares are not producing adequate milk. (This dose is equivalent to 5 ml per 500 kg – 5 ml per horse – daily, PO of the 11% oral gel.) Do not administer with stomach antacids such as omeprazole, cimetidine, or antacids.

The prokinetic effects in horses are not very impressive. At an IV dose of 0.2 mg/kg it was effective at restoring motility in horses with ileus, but this drug is not available in an injectable formulation. The oral absorption in horses is only 1.2–1.5%. Oral administration of 1.1 mg/kg (the approved dose) had no effect on GI function in horses but at 5 mg/kg it increased stomach emptying (Nieto et al., 2013).

Another use of domperidone is to increase digital laminar microvascular blood flow in horses. This effect is presumed to be via the action as an antagonist on vascular α_2-adrenergic receptors. It was shown to increase laminar microvascular blood flow in normal horses (1.1 and 5.5 mg/kg oral), but has not been evaluated clinically for treatment of laminitis (Castro et al., 2010).

Cisapride

In July 2000, cisapride (formerly called Propulsid®) was removed from the market because of serious cardiac adverse events, and some deaths in people, secondary to cardiac arrhythmias. The drug sponsor has no plans to market this drug to veterinarians, but there is continued interest among veterinarians and it is still available via compounding pharmacists. Until other new replacement drugs become available, such as prucalopride or mosapride, veterinarians will rely on compounded formulations or consider alternative drugs.

The reviews on cisapride by Washabau and Hall (1995) and Van Nueten and Schuurkes (1992) describe the details of its mechanism of action and clinical effects. Cisapride has greater prokinetic effects in comparison to the other drugs discussed thus far. Its mechanism is believed to be as an *agonist* for the 5-hydroxytryptamine ($5\text{-}HT_4$) receptor on myenteric neurons ($5\text{-}HT_4$ ordinarily stimulates cholinergic transmission in the myenteric neurons). (Serotonin and antagonists/agonists are covered in more detail in Chapter 19.) Cisapride may also be an *antagonist* for the $5\text{-}HT_3$ receptor. Via these mechanisms – or independently – cisapride may enhance release of acetylcholine at the myenteric plexus. There is evidence that, in cats, cisapride directly stimulates smooth muscle motility via an unknown noncholinergic mechanism (Washabau and Summarco, 1996). Cisapride increases the motility of the stomach, increases stomach emptying, and increases motility of the small intestine and colon. It accelerates the transit of contents in the bowel and intestines. Because of the $5\text{-}HT_3$ antagonist properties, it also has some antiemetic effects. Other drugs with a similar mechanism of action have been investigated, but are not in clinical use. One such drug is mosapride. Like cisapride, mosapride is also a $5\text{-}HT_4$ agonist and has been approved in some countries for treating upper gastrointestinal motility disorders in dogs (Chae et al., 2015). It has been studied in experimental horses and demonstrated to increase motility of the small intestine and cecum at a dose of 1.5–2 mg/kg PO (Sasaki et al., 2005).

Pharmacokinetics

Oral absorption is variable because of extensive metabolism. The oral absorption in dogs and cats ranges from 30 to 60%. In horses, rectal absorption has been attempted, but the amount absorbed systemically is negligible (Cook et al., 1997).

Elimination half-life is variable, but ranges from an average of approximately 5 hours in dogs and cats to a much faster rate in large animals, 2 hours or less in horses and ruminants. The volume of distribution is high in small animals (>4 l/kg) and approximately 1.5 l/kg in large animals.

Use in Dogs

In dogs at a dose of 0.1 mg/kg (range 0.08–1.25 mg/kg) orally, it stimulates smooth muscle of the stomach, small intestine, and colon, with a duration of effect of about 3 hours. Routine clinical doses have ranged from 0.1 to 0.5 mg/kg every 8–12 hours.

Although cisapride has been used by some veterinarians for treatment of megaesophagus in dogs, the response is usually poor. The canine esophagus is striated muscle, with no smooth muscle to directly respond to the medication. Clinical use in dogs has included treatment for gastroesophageal reflux, delayed gastric emptying, and small bowel motility disorders. Compared to metoclopramide, cisapride is more effective for increasing lower esophageal sphincter tone in dogs, which is helpful for preventing reflux esophagitis (Kempf et al., 2014).

Use in Cats

Experiments have demonstrated that cisapride causes stimulation of the entire GI tract in cats. Of particular interest is the effect of cisapride on colonic smooth muscle. Cisapride will stimulate this motility and has been used for treating chronic constipation. By contrast, metoclopramide has no effect on colonic smooth muscle. The dose of cisapride in cats is approximately 2.5 mg per cat, two or three times daily. Doses as high as 1 mg/kg every 8 hours, or 1.5 mg/kg every 12 hours have been recommended by some investigators (LeGrange et al., 1997).

Use in Horses

In horses cisapride increases the motility of the left dorsal colon and improves ileocecocolonic junction coordination. In contrast to metoclopramide, cisapride has fewer side effects at doses needed to affect the GI tract and greater effects on the jejunum and colon than metoclopramide. Many investigators believe that it has a place in the postoperative management of horses that have undergone abdominal surgery. One dose tested to be effective was 0.1 mg/kg, IV. At this dose, the effects appear to persist for approximately 2 hours. Oral administration is usually not possible in these horses because of gastric reflux and absorption after oral administration in a horse with gastric reflux probably is questionable.

Availability of Formulations

The previously available tablet was a 10-mg tablet from Janssen Pharmaceutica. Although cisapride is insoluble in most aqueous solutions, solubility is possible in acidic solutions. An IV form may be created by preparing a 4 mg/ml solution in tartaric acid by a reputable compounding pharmacist. The preparation of this formulation was described in the publication by Cook et al. (1997). To prepare this solution, 40 mg of cisapride is combined with 1 ml of 0.4 M tartaric acid. After the cisapride is dissolved, dilute with water to obtain a total volume of 10 ml. Oral formulations for cats have been prepared from the bulk powder administered in a capsule, via a suspension in a flavored vehicle or dissolved in cod liver oil.

Side Effects and Interactions

Adverse effects have not been reported in animals; however, abdominal discomfort has been observed when animals received high doses. In safety studies, dogs have tolerated high doses (40 mg/kg) for prolonged periods without problems.

In people, high plasma concentrations have caused cardiac arrhythmias. The arrhythmias are caused by prolonged QT intervals, presumably from blockade of potassium channels. This can lead to serious arrhythmias and has been responsible for deaths in people. These reactions have not been reported for animals. Nevertheless, one should be cautious about combining cisapride with drugs such as itraconazole and ketoconazole that may increase plasma concentrations by interfering with metabolism.

Bethanechol (Urecholine)

Many of the formulations of bethanechol have been discontinued and are no longer marketed. Some generic forms may still remain and veterinarians have also obtained it through compounding pharmacies. This drug is a cholinergic agonist that has been used to nonspecifically stimulate smooth muscle. It binds to muscarinic receptors and initiates GI smooth muscle contractions, but its actions are nonspecific. In contrast to cisapride or metoclopramide, bethanechol has a more pronounced effect on motility of the ileocecocolic region in cattle (0.7 mg/kg). In horses, bethanechol increases gastric emptying at a dose of 0.025 mg/kg IV (Ringger et al., 1996). One of its other uses has been to stimulate contraction of bladder smooth muscle in animals that have a failure to completely empty their urinary bladder when voiding. Adverse effects are common and include diarrhea and other consequences of cholinergic stimulation.

Neostigmine (Prostigmin)

Neostigmine inactivates the enzyme acetylcholinesterase, which results in inhibition of degradation of acetylcholine at the synapse. It prolongs the action of acetylcholine and may directly stimulate cholinergic receptors. It is short acting. In horses, its use is discouraged because it may actually decrease intestinal propulsive contractions, delay gastric emptying, and cause abdominal discomfort.

One of the other uses of neostigmine in animals is for the treatment of neuromuscular diseases such as myasthenia gravis. Its adverse effects are significant, and include diarrhea, salivation, respiratory difficulty, vomiting, and muscle twitching. (Usually, another anticholinesterase drug, pyridostigmine, is preferred for treating myasthenia gravis because it has fewer side effects.)

H_2-Receptor Antagonists

H_2-receptor blockers such as ranitidine and nizatidine have prokinetic effects on intestinal smooth muscle in animals. These drugs are discussed later in Section Drugs for Treatment of Gastrointestinal Ulcers in Animals.

Erythromycin

Erythromycin is a macrolide antibiotic ordinarily used to treat bacterial infections. Pharmacology of macrolides is discussed in Chapter 36. It has long been associated with vomiting and regurgitation in small animals as an adverse consequence of treatment. This effect is caused by stomach contraction and expulsion at high doses. However, at low doses it can produce a beneficial stimulation of GI motility. Not all macrolide antibiotics exhibit this property because it requires a unique chemical structure that not all drugs in this class possess. (Erythromycin has a 14 carbon structure, but other macrolides that are less effective – tylosin and tilmicosin – have a 16 carbon structure.)

Erythromycin stimulates GI motility via activation of motilin receptors, via release of endogenous motilin, or via cholinergic mechanisms in the upper GI tract (Hall and Washabau, 1997; Lester et al., 1998; Hawkyard and Koerner, 2007). Motilin is a 22 amino acid peptide released from endocrine cells of duodenal mucosa. It increases the motor contractions, the housekeeper wave, during the interdigestive period. Motility is stimulated specifically in the pyloric antrum or the smooth muscle cells of the proximal small intestine (Nouri and Constable, 2007; Nouri et al., 2008). Because most of the motilin receptors are on the stomach and proximal small intestine, there is a weak response to erythromycin in the distal GI tract. In people, erythromycin has been used to promote gastric motility and increase stomach emptying in patients with diabetic gastroparesis and used in conjunction with enteral feeding in critical care patients (Hawkyard and Koerner, 2007).

The effective dose is 1 mg/kg or less – much lower than the antibacterial dose. It was effective for stimulating motility in experimental horses (Ringger et al., 1996), but clinical responses to erythromycin in horses have been somewhat disappointing. One study showed that responses to erythromycin in horses that had undergone surgery were not as effective as the effects in healthy horses (Roussel et al., 2000). A dose of 8.8 mg/kg IM increased abomasal and rumen motility in calves (Nouri and Constable, 2007; Nouri et al., 2008; Wittek and Constable, 2005). The dose in small animals is also in the range of 0.5–1 mg/kg, but has not been tested for clinical efficacy (Whitehead et al., 2016). There is a concern that erythromycin may cause diarrhea in some horses through the effect on the normal bacterial flora of the intestine. An additional concern is that routine use may promote antibacterial resistance.

Lidocaine

Lidocaine is a well-known local anesthetic. (Local anesthetics are covered in more detail in Chapter 15, and with antiarrhythmics in Chapter 22.) It is used for local infiltration for minor surgical procedures and to treat cardiac arrhythmias. Intravenous infusions of lidocaine also improve intestinal motility in horses. Lidocaine has been used in horses postsurgically to reduce postoperative ileus. Postoperative ileus in horses is a widespread clinical problem that may be caused by (i) sympathetic stimulation, (ii) pain, or (iii) inflammation. These effects inhibit smooth muscle motility in the intestine and lidocaine may work by suppressing this transmission. Another view on the mechanism is that lidocaine does not have a direct prokinetic effect, but rather restores motility via other mechanisms (Cook and Bilkslager, 2008). These authors presented evidence that in horses lidocaine restores motility by inhibiting intestinal inflammation and reperfusion injury.

In one study (Malone et al., 2006), lidocaine administration to horses produced less reflux and shorter time of hospitalization. Infusions of lidocaine have decreased postoperative ileus either through a direct effect, or via suppression of painful stimuli. Doses in horses are 1.3 mg/kg loading dose (bolus), followed by 0.05 mg/kg/min IV infusion.

Adverse Effects

As with the other uses of lidocaine, systemic administration may produce adverse events. The most common in horses have been muscle fasciculations, ataxia, and seizures. If signs are observed, decrease rate of infusion.

Opiate Antagonists for Promoting Intestinal Motility

Opiates and their antagonists are discussed in Chapter 13. Activation of opiate μ receptors in the intestinal smooth muscle decreases propulsive motility. Expression of μ-opiate receptors have been found in the submucosal plexus, myenteric plexus, and longitudinal muscle of the ileum. Activating these receptors has been used to treat some forms of diarrhea (e.g., loperamide). Administration of opiate analgesics postoperatively (Boscan et al., 2006; Sojka et al., 1988) or increased levels of endogenous opioids (endorphins), stimulate these receptors to inhibit intestinal motility causing postoperative ileus (DeHaven-Hudkins et al., 2008). Therefore, postoperative ileus may be treated by blocking intestinal opiate receptors (μ receptors) (Hicks et al., 2004).

Selective peripheral opiate antagonists act as peripheral opioid antagonists, rather than central opioid antagonists. They do not produce a central effect because they are unable to cross the blood–brain barrier. *Naloxone should not be used for this indication because it will cross the blood–brain barrier to diminish the analgesic effect of opioids.* Such agents include alvimopan, methylnaltrexone, and naloxegol.

Alvimopan (Entereg®) has advantages over methylnaltrexone with respect to potency and duration of activity (DeHaven-Hudkins et al., 2008; Taguchi et al., 2001). It is administered orally with low bioavailability (6%) and produces a local effect on the intestine to promote motility, without diminishing analgesic effect of opioids. It is a zwitterionic molecule and the high polarity restricts its diffusion across the blood–brain barrier. A dose of 3 mg orally to people, three times daily completely reversed the GI effects of morphine, without affecting analgesia. The typical dose is 12 mg (one capsule) administered orally prior to surgery, and continuing after surgery twice daily.

Methylnaltrexone (Relistor®) is available as a SC injection (0.15 mg/kg) administered once every 48 hours for postoperative ileus. Like alvimopan, it does not have systemic effects and will not interfere with analgesia. There has been limited use of methylnaltrexone in horses. At a dose of 0.75 mg/kg IV q 12 h for four days to horses inhibited morphine-induced intestinal effects (Boscan et al., 2006).

Naloxegol (Movantik®), in 12.5 and 25-mg tablets, is a pegylated opioid antagonist. It is used for oral treatment of opioid-induced constipation. It acts peripherally because pegylation of the molecule reduces the ability of naloxegol to cross the blood–brain barrier and makes it a substrate for the efflux transporter P-glycoprotein.

Drugs for Treatment of Gastrointestinal Ulcers in Animals

Histamine H_2-receptor antagonists, sucralfate, proton pump inhibitors (omeprazole), and antacids remain the principal drugs used to manage gastrointestinal ulceration in small and large animals (Table 46.3; Figure 46.1). The medical management of ulcer diseases will not be covered in this section, but readers are referred to other references for this information (Merritt, 2003; Papich, 1993; Matz, 1995; Henderson and Webster, 2006a, 2006b; Feldman and Burton, 1990).

Table 46.3 Antiulcer drugs: clinical uses

Gastritis

Hypergastrinemic syndromes
Prevention and treatment of NSAID-induced ulcers

Because many of the ulcerative diseases encountered in veterinary medicine are induced by drugs that inhibit prostaglandin synthesis (nonsteroidal antiinflammatory drugs, NSAIDs), one should be familiar with the role of prostaglandins in the GI tract, how their synthesis is inhibited, and treatments used to maintain the protective effect of prostaglandins in the GI tract. Veterinarians also should be familiar with the normal physiological role of protective mucus layer in the stomach, the cytoprotective mechanisms, role of bicarbonate secretion, and the normal mechanisms that restore epithelial cells in the stomach and intestine. These factors were reviewed by Allen et al. (1993) several years ago, but are still relevant today. When these protective factors become disrupted or compromised, ulcers can occur in animals. Gastrointestinal ulcers are a major health problem in horses, pigs, dogs, cats, and zoo animals. Conditions that increase the risk of gastrointestinal ulceration are administration of ulcerogenic drugs (NSAIDs, corticosteroids, and stomach irritants), stress, disrupted mucosal blood supply, and inflammatory diseases.

Gastrointestinal ulceration is an important medical problem in horses, in which the prevalence in animals involved in showing and racing has been listed as 81–93%, and even as high as 100% in some studies. In Thoroughbreds and Standardbreds the prevalence is was 80–95%; and in show horses it may be as high as 58%. Factors such as stall confinement, intense exercise, diet (high energy concentration in diet), and racing stress may be contributing factors. Location of ulcers in horses is primarily in the squamous epithelium (nonglandular portion). Factors that contribute to ulcers are the intermittent feeding schedule and high stomach acidity. In sick foals, ulcers also are common. Factors that contribute to ulcers in foals are NSAIDs, stress, and sepsis.

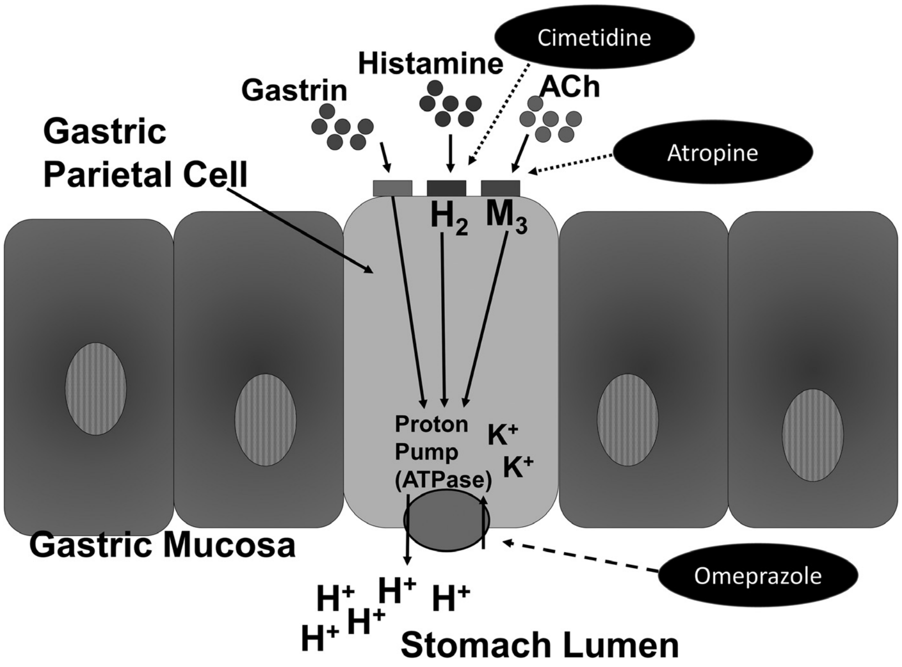

Figure 46.1 Action of stomach antisecretory drugs on various receptors that stimulate acid secretion. Action of H_2-receptor antagonists (e.g., cimetidine) and proton pump inhibitors (omeprazole) are shown. Gastrin and acetylcholine (Ach) are Ca^{++}-dependent pathways and the histamine H_2 is a cAMP-mediated pathway. See text for details.

Antacids

The common antacids are bases of either aluminum, magnesium, or calcium. Examples include aluminum hydroxide ($Al(OH)_3$), magnesium hydroxide ($Mg(OH)_2$), and calcium carbonate ($CaCO_3$, e.g., Tums®). These drugs neutralize stomach acid through a simple reaction to form water and a neutral salt. They have no systemic effects. In addition to their acid-neutralizing ability, antacids may benefit patients by decreasing pepsin activity, binding to bile acids in the stomach, and stimulating local prostaglandin (e.g., PGE_2) synthesis.

Formulations

These drugs are common and almost always available over-the-counter (OTC). Commonly available antacid preparations (e.g., Maalox®, Mylanta®, DiGel®) are combinations of magnesium hydroxide and aluminum hydroxide to optimize the buffering abilities of each compound. These combinations balance the adverse effects of constipation from aluminum hydroxide and the laxative effect from magnesium hydroxide. One of the common products is Gaviscon®, which is popular for reflux esophagitis (heartburn) in people. The regular strength tablets contain 80 mg aluminum hydroxide and 14.2 mg magnesium trisilicate. The oral liquid contains 95 mg aluminum hydroxide and 358 mg magnesium carbonate per 5 ml (mint flavor). The tablets must not be swallowed whole and should be chewed, which should be considered before using the tablets for pets.

Adverse Effects / Interactions

Adverse effects from antacids are rare because they are seldom administered long term. Additionally, antacids are not absorbed and therefore lack serious systemic effects. In animals with kidney disease, magnesium accumulation may be a problem. For example, Gaviscon® oral suspension contains 115 mg magnesium per 5 ml. Antacids will interfere with the oral absorption of other drugs (e.g., tetracyclines, fluoroquinolones, and digoxin), if administered concurrently. The magnesium component, like any divalent cation (Mg^{++}) can chelate with fluoroquinolones or tetracyclines and inhibit oral absorption. If these drugs are used together, administer the antibiotic 2 hours prior to the antacid drug. Oral antacids also reduce stomach acid, which affects oral absorption of some medications, particularly oral azole antifungal drugs. This is discussed with the drug interactions for other acid-suppressing drugs in Section Drug Interactions with Proton Pump Inhibitors.

Dosing Recommendations

Dose recommendations vary and are not precisely determined for dogs and cats. Empirically, 5–10 ml six times daily for small animals is often cited, regardless of the animal's size or product used. The frequency of administration is a significant disadvantage for administration to pets; therefore, if long-term acid suppression is needed for dogs or cats, other agents are used (see other drugs in Section Drugs for Treatment of Gastrointestinal Ulcers in Animals). Doses of 180 to 250 ml have been administered to adult horses, but only suppressed acidity for

45 min to 2 hours (Murray, 1997). A dose of 30–60 ml for calves and foals has been recommended. For the treatment of acid rumen, magnesium hydroxide has been administered orally at a dose of 225–440 grams per adult cow, or mineral oil at 4 liters per rumen. For the treatment of grain overload, antacids have been administered at a dose of 450 grams per rumen, repeated every 6–8 hours.

Histamine H_2-Receptor Antagonists

These drugs include cimetidine (the first in this class), ranitidine, famotidine, and nizatidine. These drugs became extremely popular after the initial release in the 1980s, but the use has declined because of the more potent and longer-acting proton pump inhibitors (discussed in Section Proton Pump Inhibitors). Blockade of histamine H_2 receptors inhibits gastric acidity that can be beneficial for ulcer healing in the stomach and duodenum. In animals the evidence for efficacy – based on data generated from controlled studies – is lacking. In studies that have measured stomach acidity, or compared results with proton pump inhibitors (e.g., omeprazole) the H_2-receptor antagonists were less effective. Nevertheless, many veterinarians continue to administer cimetidine, ranitidine, and famotidine with the impression that they are beneficial for the treatment of gastric and duodenal ulceration, gastric erosions, esophageal reflux disease, and gastritis in animals. There are various drugs in this group. They vary in their potency (Table 46.4) and in their pharmacokinetics, but there is no evidence for differences in efficacy among the drugs.

Mechanism of Action

Acid secretion is stimulated by three receptors (Figure 46.1): (i) gastrin receptor, (ii) histamine type-2 (H_2 receptor), and (iii) cholinergic (muscarinic) receptor (M_3). Stimulation of acid secretion occurs via stimulation of all three receptors. H_2-receptor antagonists effectively block gastric acid secretion from parietal cells by blocking the H_2 receptor.

Use in Small Animals

The use of the oldest drug in this group, cimetidine, has diminished in favor of the other drugs. Cimetidine has been administered to dogs at doses of 10 mg/kg (IV, IM, or orally), and ranitidine at doses of 2 mg/kg (IV, IM, or orally), but dosing frequency is not well-established. Famotidine (Pepcid®) has been used at 0.5 mg/kg q 12–24 h, but doses of 0.1–0.2 mg/kg q 12 h are probably equally effective. Despite the availability of pharmacokinetic information, a precise dose interval for the drugs listed has not been established because the optimum duration or extent of acid suppression for ulcer healing to occur is not known.

Table 46.4 Potency of histamine H_2 receptor blocking drugs

Drug	Relative potency
Cimetidine (Tagamet®)	1
Ranitidine (Zantac®)	4–10
Nizatidine (Axid®)	4–10
Famotidine (Pepcid®)	20–50

Use in Horses

Suppression of gastric acidity in horses was reviewed by Murray (1997). These drugs are not absorbed orally in horses as well as in dogs, with a systemic availability of only 14–30%, and the high oral doses for large animals reflect this difference (Sams et al., 1997). Cimetidine is rarely used in horses anymore because of the availability of other drugs. The dose previously used in horses was 40–60 mg/kg/day. Ranitidine has been used in horses at a dose of 2.2–6.6 mg/kg q 6–8 h (Holland et al., 1997). In clinically normal foals, ranitidine at 6.6 mg/kg, PO, or 2 mg/kg IV suppresses acid secretion for 8 hours and 4 hours, respectively (Sanchez et al., 1998).

Use in Calves

Cimetidine and ranitidine have been used in calves to maintain the pH of the abomasum >3.5 for 75% of the dosing interval (Ahmed et al., 2001). Recommended oral doses are cimetidine 100 mg/kg q 8 h, or ranitidine 50 mg/kg q 8 h.

Adverse Effects

Generally, histamine H_2-receptor antagonists have a good safety record. Adverse effects reported in people include antiandrogenic effects, decreased reproductive performance, central nervous system toxicity, and bacterial overgrowth in the stomach. These effects are rare and have not been cited as a serious problem in veterinary patients. There have been anecdotal reports of famotidine injection producing hemolytic anemia in cats. However, the conclusion from a clinical study was that when administered IV over 5 minutes, there was no risk (de Brito Galvao and Trepanier, 2008). Drug interactions are possible because cimetidine inhibits the clearance of other drugs via its action as a hepatic oxidation enzyme inhibitor (microsomal enzyme cytochrome P450 inhibitor). Ranitidine and famotidine are less likely to cause such a reaction. Drug interactions also are possible because of their effects to increase stomach pH. This can affect oral absorption of some drugs that require acidity for drug dissolution. This is discussed in more detail in Section Drug Interactions with Proton Pump Inhibitors.

Other Effects of H_2-Receptor Antagonists

Histamine H_2-blocking drugs have been used for other conditions in addition to suppressing stomach acid. Some evidence suggests that cimetidine strengthens the gastric mucosal defenses against ulceration (e.g., increases bicarbonate secretion), and enhances cytoprotection, but the relationship of these effects to ulcer healing are not well understood.

Effects on smooth muscle activity: Acid secretion inhibits stomach contractions. In experimental dogs, administration of cimetidine normalized the stomach contractions that were inhibited by stimulation of acid secretion in the stomach. Therefore, H_2-receptor antagonists may have a role in promoting an emptying of the stomach (Hayashi et al., 1990). In addition, ranitidine and nizatidine, but not cimetidine or famotidine, stimulate motility and increase gastric emptying and colonic motility via an anticholinesterase (AchE) action. Because of these motility effects, ranitidine has been used to stimulate GI motility as a prokinetic agent in animals.

Immunological effects: Cimetidine can block H_2 receptors on suppressor T lymphocytes, which increases lymphocyte responses to mitogen stimulation (Mavligit, 1987). This effect has been applied clinically in the immunological treatment of patients with tumors (Goetz et al., 1990), but the clinical benefit for most uses has been controversial. In people, the administration of cimetidine may accelerate healing of herpes lesions in immunocompromised patients.

Antiallergic effects: Histamine H_2 blockers may decrease the effects of histamine on blood vessels, and may alleviate some inflammation due to allergy. However, when used as a sole treatment, the clinical response has not been encouraging. Ordinarily when antihistamine effects are desired for treating allergic conditions, histamine type 1 (H_1) antagonists are administered.

Sucralfate (Carafate®)

Sucralfate dissociates in the acid milieu of the stomach to sucrose octasulfate and aluminum hydroxide (Figure 46.2). Sucrose octasulfate polymerizes to a viscous, sticky substance that creates a protective effect by binding to ulcerated mucosa. It protects the mucosa by preventing

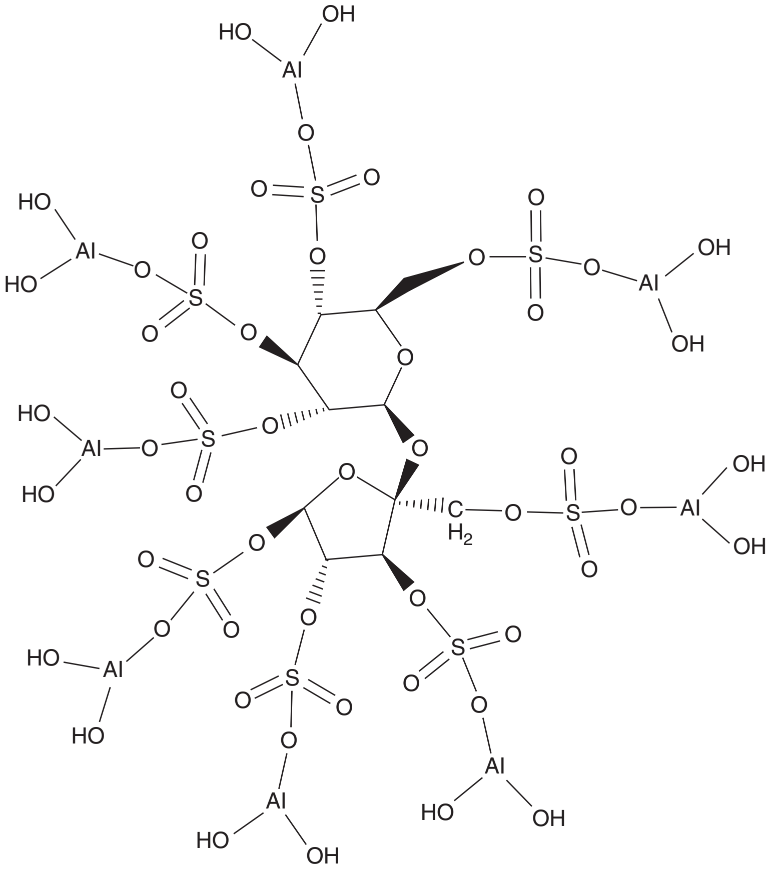

Figure 46.2 Sucralfate structure.

back diffusion of hydrogen ions and also inactivates pepsin and adsorbs bile acid. Additionally, sucralfate increases the mucosal synthesis of prostaglandins, which has a cytoprotective role and may promote healing. Increase in the epidermal growth factor may contribute to ulcer healing.

Clinical Use

Sucralfate can be beneficial for treatment of gastric ulcers in animals, but there is no evidence that it is effective for prevention of gastritis or gastric ulcers. Some veterinarians have used sucralfate to prevent ulcers caused by nonsteroidal antiinflammatory drugs (NSAIDs). Despite this common use, there is little evidence of its efficacy for preventing NSAID-induced ulcers. Because sucralfate is not absorbed, it is virtually free of adverse effects. The most common side effect associated with its use in people has been constipation. Dosage regimens for sucralfate have been extrapolated from human dosages. Doses administered are as follows: 250 mg (one-quarter tablet) to cats two to three times daily, 500 mg to 1 gram to dogs, and 4 grams orally to foals. The tablets must disintegrate to produce a therapeutic effect. In studies performed in dogs, there is evidence that the intact tablets do not disintegrate and crushing the tablets and administering as a liquid suspension may be more effective (KuKanich and KuKanich, 2015).

Drug Interactions

Even though sucralfate has some "coating action," this does not prevent oral absorption of drugs from the intestine. However, sucralfate contains aluminum and may interfere with absorption of some drugs. For example, aluminum will chelate fluoroquinolone and tetracycline drugs and inhibit oral absorption (KuKanich and KuKanich, 2015; KuKanich et al., 2016). However, the effects on fluoroquinolone absorption in dogs are inconsistent (KuKanich et al., 2016). If these antibiotics are needed, administer them first, 30 minutes to 2 hours prior to sucralfate administration.

Table 46.5 Proton pump inhibitors (PPI)

Omeprazole (Prilosec®) 20 mg capsule and other forms
Lansoprazole (Prevacid®) 20 mg tablet
Rabeprazole (Aciphex®) 20 mg tablet and IV
Pantoprazole (Protonix®) 40 mg tablet, and IV
Esomeprazole (Nexium®) 20, 40 mg capsules
Dexlansoprazole (Kapidex®) 30, 60 mg capsules

Proton Pump Inhibitors

Gastric acid secretion is stimulated by hormonal and neural stimulation of parietal cells, which are located in the proximal stomach (Figure 46.1). The proton pump inhibitors (PPI; omeprazole, pantoprazole, esomeprazole) (Table 46.5) are substituted benzimidazole drugs that target the final common pathway of acid production. These drugs have emerged as more effective and widely used than the previously discussed histamine type-2 antagonists (Barkun et al., 2012). The PPIs are weak bases that are unprotonated and act as prodrugs in the physiological pH of the blood. After systemic absorption, they become trapped in the acidic parietal cells of the stomach (Figure 46.3). Once the PPI diffuses and accumulates in the acidic environment of the secretory canaliculi of the active parietal cell (up to 1000 times the plasma concentration), it becomes protonated and trapped, where it forms disulfide bonds with cysteine residues on the alpha subunit of the H^+-K^+-ATPase enzymes, resulting in prolonged to irreversible enzyme inactivation (Kromer et al., 2000). The effect is prolonged because acid secretion resumes only after new proton pumps are synthesized in the parietal cells. There may be an initial delay before achieving maximal efficacy. Previously dormant parietal cells are activated following initial PPI administration. Thus, inhibition of acid secretion is approximately 30% of maximal on day 1 of PPI administration since not all H^+-K^+-ATPase enzymes are bound by drug. Maximal inhibitory effect is thought to be achieved within

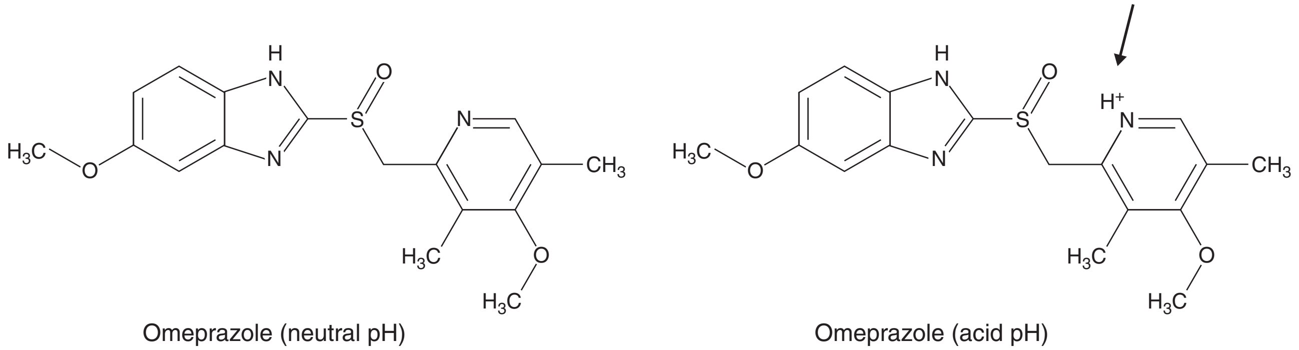

Figure 46.3 Omeprazole structure. At neutral pH the structure has no charge, but after entering the acidic parietal cell, it picks up a positive charge (shown by arrow), to "trap" the drug in the cell.

approximately 2–4 days of PPI administration (Kromer et al., 2000; Larsson et al., 1983; Abelo et al., 2002; Wallmark et al., 1985). Because the inhibitory activity of a PPI is dependent on its ability to accumulate in the parietal cell and bind to active H^+-K^+-ATPase enzymes, the plasma concentrations of PPIs do not necessarily predict their efficacy. The best surrogate predictors of the inhibitory effect of PPIs on gastric acid secretion are the area under the concentration–time curve and gastric pH profile (Andersson et al., 2001).

The delay in the maximum activity of PPI is also related to the stability of these drugs in the stomach. They are acid-labile drugs and when administered in an acid environment, the drug may be degraded before it reaches the intestine where it can be absorbed systemically. After repeated administration, acid secretion gradually diminishes, thus maximizing the amount of active drug absorbed from the intestine (Prichard et al., 1985). Initial treatment with intravenous formulations (e.g., pantoprazole), administering an enteric-coated delayed-release formulation, or combining oral formulations with bicarbonate (Zergid® is an example of a combination of omeprazole and sodium bicarbonate) will decrease the lag-time for achieving maximum effect. Another theory to explain the increased concentrations with repeated doses is an inhibition of the cytochrome P450 enzymes by omeprazole, thus inhibiting its own metabolism (Andersson et al., 1990). Omeprazole is a well-known inhibitor of the enzyme CYP 2C19 in people, but it is not known which enzymes (if any) are inhibited in dogs or cats.

Pharmacokinetics and Metabolism

Cytochrome P450 (CYP) enzymes are responsible for the metabolism of the majority of the PPIs. The exception being rabeprazole, which is unique among the PPIs in that the CYP system is only responsible for 15–20% of its metabolism (Yasuda et al., 1995). Genetic polymorphism in CYP genotypes is a well-established cause for the large interindividual and interethnic variation in the pharmacokinetics and pharmacodynamics of PPIs in humans (Egan and Murray, 2000). There are differences in response among animals, but not enough work has been done to determine if this is caused by differences in CYP expression among animals. The pharmacokinetics have been extensively studied in horses (Sykes et al., 2014, 2015a, 2015b, 2016). Differences in pharmacokinetics exist for various formulations, but these differences may not account for clinical efficacy differences. More discussion of the formulations is provide in the Section Clinical use and efficacy in horses.

Clinical Use

Acid secretion is activated by ingestion of a meal. Therefore, it is recommended to administer most PPIs 30 minutes to 1 hour prior to a meal to minimize the effects of stomach acidity on oral absorption, and to ensure that maxim absorption occurs so that the drug is in circulation and available to accumulate in the parietal cell prior to meal-stimulated acid secretion. If administered once daily, morning administration is recommended because the prolonged fast results in higher number of H^+-K^+-ATPase enzymes available to mobilize to the secretory canaliculi (Chiverton et al., 1992). Newer PPIs such as the R enantiomer of lansoprazole, dexlansoprazole, are designed to be slow release and effective against both basal and meal-stimulated acid secretion, thus gastric pH may not be impacted by the timing of meal intake and administration of newer PPIs (Lee et al., 2009). There is evidence in humans that these drugs are superior to other antisecretory drugs such as histamine H_2-antagonists for treatment and prevention of ulcers caused by NSAIDs. In human studies, omeprazole has had better healing rates in comparison to other antiulcer drugs – such as H_2-receptor blockers – for some types of ulcers and esophagitis. In addition, these drugs have an inhibitory effect on the bacteria *Helicobacter pylori*, which is a cause of gastritis and ulcers in people.

Clinical use and efficacy in dogs and cats: Despite their widespread use in companion animals, there have been limited clinical studies investigating the efficacy of PPIs in companion animals. Far more clinical efficacy studies exist for horses, where they have FDA-approved products in the USA and other countries (Sykes et al., 2015a, 2015b). The majority of canine and feline PPI studies were designed as preclinical development trials prior to study of these drugs in humans. Many of these studies were performed following pharmacological stimulation of gastric acid secretion using healthy animals with surgically placed gastric fistulas. It is unknown if results from these studies accurately reflect the response of intragastric pH to PPIs in clinical canine and feline patients. Comparison studies performed in healthy dogs and cats with neither of these interventions demonstrated that PPIs are superior to histamine H_2 antagonists for raising and maintaining high intragastric pH and for prevention of exercise-induced gastritis in dogs (Bersenas et al., 2005; Tolbert et al., 2011; Parkinson et al., 2015; Sutalo et al., 2015). A typical human dose of omeprazole is 20 mg. A full 20-mg capsule has been administered to dogs, regardless of weight. Alternatively, doses of 0.7–1 mg/kg administered once or twice daily has been used most often. Early studies in dogs and cats used once-daily administration, but results from other studies in healthy dogs and cats suggest that omeprazole should be administered twice daily to achieve pH goals established for the treatment of acid-related disorders in people (Bersenas et al., 2005; Tolbert et al., 2011; Sutalo et al., 2015; Burget et al., 1990; Bell et al., 1992). There have been no benefits demonstrated for the coadministration of histamine H_2 antagonists and PPI in animals (Tolbert et al., 2015).

Clinical use and efficacy in horses: The use in horses is widespread because as discussed in Section Drugs for Treatment of Gastrointestinal Ulcers in Animals, performance horses have a high incidence of gastric ulcers. Omeprazole is most often used because of approved formulations developed for horses (Sykes et al., 2015a, 2015b, 2016). A dose of 1 mg/kg/day is needed to inhibit acid secretion (Andrews et al., 1999) and 1.4–2 mg/kg is needed for a more consistent effect (Baker and Gerring, 1993; Murray, 1997). A dose of 4 mg/kg PO suppressed acid secretion in foals for 22 hours. Omeprazole (4 mg/kg PO, q 24 h) was significantly better than ranitidine (6.6 mg/kg PO, q 8 h) for healing ulcers (Lester et al., 2005). Omeprazole is approved for this use as GastroGard®, an oral paste for horses at a dose of 4 mg/kg once daily for 4 weeks, and for prevention of ulcers the dose is 2 mg/kg once daily. Three to five days of administration are required for maximal suppression of acid secretion. To promote ulcer healing in horses, the pH of the stomach should be maintained above 3.5 (Andrews et al., 1999). An over-the-counter (OTC) form of this drug for horses is also available (UlcerGuard®). The dose and concentration is the same as the prescription drug (GastroGard®). If compounded formulations are prepared – especially if prepared from a bulk chemical substance – degradation may occur in the stomach, which renders the drug ineffective (Nieto et al., 2002). Plain, uncoated omeprazole made from powder had half the bioavailability compared to the commercial formulation (Sykes et al., 2015b).

Although GastroGard®is the most common formulation, other formulations have become available for horses in some countries. Two buffered formulations are available in other countries, Omoguard® and Abgard,® and two enteric-coated granule formulations, Gastrozol® and BOVA Omeprazole Granules.® These other formulations were described, and evaluated by Sykes et al. (2015a, 2015b, 2016) (see Table 1 of Sykes et al., 2016 for descriptions). When four formulations were compared to the reference GastroGard®, there were no statistical differences in pharmacokinetics for three formulations but one (Abgard®*)* produced a lower peak concentration.

The same research group also evaluated omeprazole doses used in horses (Sykes et al., 2014, 2015a, 2015b). They found that 1 mg/kg oral per day was therapeutically equivalent to 4 mg/kg once daily for treatment of naturally occurring gastric ulcers in Thoroughbred race horses. They also found that gastric ulcers that occur in horses have lower healing rates from omeprazole if they occur in the glandular portion of the stomach compared to the squamous (nonglandular) portion of the stomach.

Adverse Effects

Despite easy access without prescription (OTC) of these products for humans and widespread use, adverse reactions are rare. Few adverse effects have also been reported with PPI use in dogs, cats, and horses. One explanation is that the effects on the gastric H^+, K^+-ATPase are not shared by other ATPases. Nongastric ATPases lack the ability to convert the prodrug to the active form, which requires an acid environment. Thus, the PPI accumulate in the acidic parietal cells of the stomach, but much less so in other cells of the body.

Two adverse consequences as a result of chronic administration of PPI have received attention. Because of loss of negative feedback mechanisms, gastrin levels are elevated as a result of PPI administration (Solcia, 1993). Consequently, persistently elevated gastrin levels exert a trophic effect on the gastric mucosa. This property has been linked to development of gastrin neoplasia in laboratory animals, specifically tumors arising from enterochromaffin-like cells in rats. This was a significant concern when these agents first became popular in the 1980s. However, after years of experience with PPI in people, this has not been demonstrated to be a realistic concern. One study has demonstrated elevated gastrin levels in cats after chronic administration (Gould et al., 2016). However, other than a transient rebound hypersecretion of acid in some of the research cats, no other adverse effects were identified. No similar studies have been done in dogs.

The second effect often discussed as a result of chronic administration of PPI is small intestinal bacterial overgrowth (SIBO) (Lo and Chan, 2013). Proton pump inhibitors increase the population of bacteria in the small intestine (Wallace et al., 2011). By increasing the stomach pH, this can potentially increase colonization of bacteria that would otherwise have been inhibited in the acid milieu of the stomach and upper small intestine. Increased survival of swallowed bacteria in the upper GI tract is influenced by other effects of PPI such as decreased intestinal peristalsis, decreased stomach emptying, changes in epithelial mucus composition, and increased bacterial translocation. Bacteria overgrowth in the small intestine can lead to some malabsorption syndromes and impaired vitamin B_{12} absorption. Increased growth of bacteria in the upper GI tract could also increase risk of more severe consequence in small animal patients with aspiration pneumonia. Studies in dogs have shown that omeprazole at a dose of 1.1 mg/kg twice daily for 15 days increased total bacteria in the duodenum (*Lactobacillus*) and a decrease in stomach *Helicobacter* spp. during omeprazole treatment (Garcia-Mazcorro et al., 2012). However the overall phylogenic composition of the gastric and duodenal microbiota did not change.

Bacterial overgrowth also can have consequences when the PPI are administered with NSAIDs. This has been a concern in people because these drugs are often prescribed together in patients at risk for upper GI injury from nonsteroidal antiinflammatory drugs (NSAIDs) (Marlicz et al., 2014). Whether or not this drug combination produces a risk in dogs, cats, or horses has not been determined.

Diarrhea is the most common adverse effect reported in association with PPI administration in dogs (Bersenas et al., 2005; Davis et al., 2003). Adverse effects have not been observed in cats. After prolonged twice-daily administration for 60 days of omeprazole to experimental cats, the study did not identify significant problems (Gould et al., 2016). There were no significant changes in magnesium, cobalamin, calcium, bone mineral density, or bone mineral content.

Drug Interactions with Proton Pump Inhibitors

Several documented, and potential, drug–drug interactions have been associated with PPI administration. The administration of PPI raises the gastric lumen pH from a normal of 1–2 units, to above 4 and sometimes higher. Some drugs and nutrients require acid for oral absorption because they exhibit pH-dependent drug solubility or dissolution. Some drugs require acid pH to release the drug from a protective coating. Therefore, administration of PPI simultaneously with some drugs may affect oral absorption, reducing the systemic exposure and clinical effect. The drugs affected by dissolution are primarily the weak bases. These drugs require acid pH to increase solubility, which is the first step in GI drug absorption (after product disintegration).

Antifungal drugs of the azole class include ketoconazole, itraconazole, and new agents voriconazole and posaconazole (discussed in Chapter 38). These drugs are inherently poorly soluble. For oral absorption to occur these drugs must undergo dissolution, which only occurs at a low pH. Subsequently, they must be administered orally with food to stimulate acid secretion. This effect was best demonstrated by the significant impairment of dissolution of ketoconazole at a high pH, and the decreased oral absorption of ketoconazole in experimental dogs caused by raising the stomach pH profile (Zhou et al., 2005).

Other drugs that may have impaired oral absorption from an increase in stomach pH include iron and mycophenolate. Hydrochloric acid in the stomach promotes iron absorption because it reduces the ferric acid form to the more soluble ferrous form. Human patients on chronic PPI therapy may have reduced oral absorption of iron. Treatment with PPI is considered in human patients with hereditary hemochromatosis in order to reduce the need for frequent phlebotomy (Hutchinson et al., 2007). The effect of chronic administration of PPI on oral iron absorption has not been explored in dogs, cats, or horses. Mycophenolate mofetil (discussed in Chapter 45) requires acid pH for dissolution of the medication and for hydrolysis to mycophenolic acid. If PPI are administered concurrently, the increased pH reduces the absorption of the active drug (Gabardi and Olyaei, 2012). This interaction has been demonstrated in people, but has not been explored in dogs or cats.

Drug interactions that affect drug metabolizing enzymes: PPI are metabolized by hepatic cytochrome P450 enzymes, and drug interactions with CYP-dependent drugs are possible because of the inhibitory effect of PPIs on the CYP system. The predominant enzyme identified in people is CYP2C19. Administration of omeprazole can inhibit its own metabolism (discussed in Section Proton Pump Inhibitors) or inhibit metabolism of other drugs metabolized by the same enzyme (Furuta et al., 2001; Mullin et al., 2009; Gerson and Triadafilopoulos, 2001). Drugs affected in people include warfarin, clopidogrel, and diazepam. The population of CYP 450 enzymes are not the same in people and dogs (Court, 2013); therefore, it is undetermined if omeprazole inhibits metabolism of these, or other drugs, in dogs.

Of interest is the effect of omeprazole on the conversion of clopidogrel (Plavix®) to the active form. Clopidogrel is a prodrug and, after administration, must be converted to the active form prior to inhibiting platelet function (discussed in Chapter 25). In people, omeprazole may inhibit one of the enzymes responsible for conversion. Concurrent administration of omeprazole and clopidogrel may interfere with the biotransformation that is responsible for the formation of the active metabolite of clopidogrel and compromise antiplatelet therapy (Laine and Hennekens, 2010). The US Food and Drug Administration (FDA) recommends that "concomitant use of drugs that inhibit CYP2C19 (e.g., omeprazole) should be discouraged." However, a study in dogs showed that, coadministration of omeprazole with clopidogrel to experimental dogs did not diminish the antiplatelet effects of clopidogrel (Thames et al., 2017). These effects have not been studied in cats or horses.

Synthetic Prostaglandins

Synthetic prostaglandins – administered orally – produce many of the protective effects on the GI mucosa of natural prostaglandins (Allen et al., 1993; Henderson and Webster, 2006a, 2006b). Misoprostol (Cytotec®) is a synthetic PGE_1 analogue that has been used in people to diminish the risk of ulcers associated with NSAID therapy. In dogs, it prevents duodenal hemorrhage and ulceration associated with aspirin therapy, but has not been tested with other NSAIDs in small animals. Misoprostol is helpful for preventing GI ulcers, but is less beneficial for treating ulcers once they occur. Its use appears to be limited to NSAID therapy. Misoprostol was *not* effective for preventing gastritis, ulcers, and gastrointestinal hemorrhage associated with corticosteroid administration (Hanson et al., 1997).

Use in Small Animals

Misoprostol is available as 0.1 and 0.2-mg tablets. Dosages for dogs range from 2 to 5 μg/kg. It is absorbed and rapidly metabolized to an active metabolite. At high doses (>5 μg/kg) adverse effects of diarrhea have been reported.

Use in Horses

Misoprostol has been shown to decrease stomach acidity in horses. However, misoprostol may cause abdominal discomfort, cramping, and diarrhea. There have been anecdotal benefits for treating or preventing right dorsal colitis in horses associated with phenylbutazone treatment. However, more safety and efficacy data are needed before the clinical use is established.

Nongastrointestinal Uses for Misoprostol

Misoprostol was shown to have modest antiinflammatory effects and has been effective for some dermatoses in dogs. In these studies, 3–6 μg/kg was administered to dogs with atopic dermatitis three times daily orally. Misoprostol produced a decrease in pruritus and clinical score of 30%. Side effects may prevent more widespread use and higher doses.

Misoprostol is an effective abortifacient. It has been used as a component of medical treatment of abortion in humans, in combination with other drugs. The protocol in people is 200 mg mifepristone (RU-486) oral, followed by 800 mg misoprostol 24–48 hours later. This protocol has not been used in animals, but if it is administered inadvertently to a pregnant animal, abortion could occur.

Drugs Used to Treat *Helicobacter* Gastritis

Treatment of gastritis and ulcers caused by the bacteria *Helicobacter pylori* and *Helicobacter*-like organisms has been used in animals that have not responded to other treatments. These organisms have been identified in biopsy specimens from dogs and cats, but its role in gastritis and ulcers has yet to be established (Yamasaki et al., 1998). Some studies have found no association between *Helicobacter* infection and gastritis (Winberg et al., 2005; Haponen et al., 1998). However, in some animals with gastritis, treatment has helped decrease signs when treatment was initiated with ampicillin, metronidazole, and famotidine. A discussion on the role of *Helicobacter* as a cause of gastritis in animals can be found in the articles by Simpson et al. (2000) and Neiger and Simpson (2000). One of the authors recommends that animals with clinical signs of gastritis and positive for *Helicobacter* or *Helicobacter*-like organisms should be treated. The oral treatment for animals that has been the most widely used is a 2-week course of the combination of metronidazole and/or clarithromycin, plus amoxicillin, and a proton-pump inhibitor, or H_2-receptor antagonist.

In people, *Helicobacter pylori* gastritis has been treated with the simultaneous use of metronidazole, omeprazole, and clarithromycin (Suerbaum and Michetti, 2002). One regimen uses clarithromycin (Biaxin®) and omeprazole (Prilosec®). A product called Tritec® combines ranitidine with bismuth citrate and is designed to be administered concurrently with clarithromycin (Biaxin®). Some regimens also use amoxicillin or metronidazole. Some synergism is achieved with these combinations. For example, H_2 antagonists or omeprazole enhance the antibacterial activity of metronidazole and perhaps other antibiotics.

Drugs for Treatment of Diarrhea

The most important treatment for diarrhea should include fluid therapy, electrolyte replenishment, maintaining acid/base balance, and control of discomfort. But drugs such as antimicrobials, motility modifiers, and intestinal protectants are sometimes used. Many of the causes of diarrhea do not require drug therapy and the disease is self-limiting. In some instances, treatment may be needed to temporarily relieve clinical signs. Some of these treatments are discussed here. Diarrhea caused by intestinal parasites is covered in Chapters 39–42 of this book.

Mucosal Protectants and Adsorbents

Kaolin–Pectin Formulations

Products that are promoted as mucosal protectants such as mixtures of kaolin and pectin (Kao-Pectate®) have been popular. Kaolin is a form of aluminum silicate and pectin is a carbohydrate that is extracted from the rinds of citrus fruits. The manufacturers claim that kaolin–pectin acts as a demulcent and adsorbent in the treatment of diarrhea. The action of kaolin–pectin is believed to be related to binding of bacterial toxins (endotoxins and enterotoxins) in the GI tract. However, experimental studies have shown that kaolin–pectin is an ineffective binder of *E. coli* enterotoxin and clinical studies have failed to show a benefit from the administration of kaolin–pectin. This product may change the consistency of stools, but it will not decrease fluid or electrolyte loss, nor will it shorten the duration of illness.

Kao-Pectate formulations contain salicylate as one of the active ingredients. There is 8.7 mg/ml in the *Regular*

Strength, and 16 mg/ml in the *Extra Strength* formulation. Since some animals may be sensitive to salicylates, the salicylate content of the formulation should be considered before administering the product to animals.

Clinical use of kaolin–pectin: Despite the lack of clinical evidence of efficacy, some veterinarians administer this drug at a dose of 1 to 2 ml/kg, q 6 h. Kaolin–pectin is not absorbed, but salicylate may be absorbed in most animals (see Section Bismuth Subsalicylate, and Papich et al., 1987). Drug interactions are also possible. Kaolin–pectin may adsorb or bind other drugs that are administered orally and decrease their effectiveness.

Bismuth Subsalicylate

The most common form of bismuth subsalicylate is Pepto Bismol®. Although other "mucosal protectants" may have questionable efficacy, this product is considered by many gastroenterologists to be a useful symptomatic treatment for acute diarrhea. Its efficacy has been proven in controlled clinical trials in humans with acute diarrhea, particularly the form caused by enterotoxigenic *E. coli* (also known as traveler's diarrhea) (Bierer, 1990). Bismuth may have some ability to adsorb bacterial enterotoxins, and it may produce some gastric or intestinal protective effect. The salicylate component may be responsible for efficacy, because it produces an anti-inflammatory action. There are five sources of salicylate in this formulation accounting for approximately 9 mg of salicylate per ml. Two tablespoons (the typical human dose) contains almost 300 mg of salicylate. An "extrastrength" formulation contains twice this amount. Practically all of the salicylate from PeptoBismol® is absorbed systemically when administered to dogs and cats (Papich et al., 1987). Despite the systemic absorption, the amount is unlikely to produce salicylate toxicity. Even in cats – a species sensitive to salicylate toxicity – it is unlikely that enough would be administered from standard dosages to produce a toxic reaction.

Clinical use of bismuth subsalicylate: The dose administered to animals was not derived from clinical studies, but extrapolated from human dosages. One to three ml/kg/day in divided doses have been administered safely (even to cats). Some animals may not like the taste, but otherwise there have not been serious adverse effects reported from administration of PeptoBismol®. Salicylate toxicosis is possible from overdoses, and pet owners should be advised to limit the amount administered, especially in animals with other primary diseases that may have initiated the diarrhea. Pet owners should be warned that PeptoBismol® may turn the stools black. Bismuth also has an anti-*Helicobacter* effect in the stomach, and has been included in many of the regimens for treating *Helicobacter* gastritis. Therefore some benefits for treating gastritis may have been caused from the action on *Helicobacter* or *Helicobacter*-like organisms.

PeptoBismol® also has been administered for the treatment of acute diarrhea in large animals, especially foals and calves. The presumed benefit is from binding to enterotoxins or from the antiprostaglandin effect.

Motility Modifiers for Treatment of Diarrhea

Anticholinergic Drugs (Antimuscarinic Drugs)

Anticholinergic drugs significantly decrease intestinal motility and secretions and have been included as ingredients in antidiarrheal preparations. These drugs inhibit muscarinic action via their antagonism of either the muscarinic M_1 or M_3 receptor. (M_1 is a ganglionic receptor, and M_3 acts at peripheral sites.) Their parasympatholytic effects decrease segmental and propulsive intestinal smooth muscle contractions. Although they do not alter the course of the disease, anticholinergic drugs may decrease the urgency associated with some forms of diarrhea, decrease the fluid secreted into the bowel, and decrease abdominal discomfort associated with hypermotility. The limitation for the use of anticholinergic drugs lies in the questionable efficacy for most diarrhea seen in veterinary medicine (few cases of diarrhea actually can be classified as "hypermotile"). These drugs are also associated with important side effects. Anticholinergic drugs are discussed in more detail in Chapter 8.

Efficacy: Although the anticholinergic agents clearly decrease intestinal motility, there is no clear evidence that a decrease in motility is always beneficial. Intestinal motility is already impaired in many patients with some forms of diarrhea and these drugs may actually worsen the diarrhea by creating a "stovepipe" effect. The use of these drugs should be avoided if the diarrhea is infectious (e.g., caused by *Salmonella*).

Adverse effects: Anticholinergic drugs have profound systemic pharmacological effects. If they are administered in sufficient doses to affect the bowel, adverse effects are possible, which include ileus, xerostomia, urine retention, cycloplegia, tachycardia, and central nervous system (CNS) excitement. Chronic administration can lead to serious bowel atony. In addition to decreasing bowel motility, anticholinergic drugs decrease stomach emptying, which can lead to stomach distention and discomfort. This is certainly contraindicated in a patient that has gastritis and is vomiting. Rumen atony is possible in cattle.

Examples of drugs: Atropine is the best known anticholinergic drug, but because it has many other systemic

Quaternary amines
methscopolamine
isopropamide
propantheline
glycopyrrolate

effects, it is not ordinarily used for its antidiarrheal properties. To avoid CNS effects, it is desirable to administer drugs that are quaternary amines. Because these drugs are charged, their lipophilicity is reduced and they do not cross the blood–brain barrier as readily as tertiary amines (Table 46.6).

Quaternary amines used in veterinary medicine (Table 46.7) include methscopolamine, propantheline (Pro-Banthine®), and isopropamide (Darbid®). Darbazine®, an old combination rarely available today, contains both isopropamide and prochlorperazine. Anticholinergic drugs have been included in formulations such as aminopentamide in Centrine® and diphemanil in Diathal®. Combination products such as Donnatal® contain scopolamine, atropine, and hyoscyamine (in addition to phenobarbital). Some of these formulations are outdated and unavailable today.

N-Butylscopolammonium bromide (Buscopan): N-butylscopolammonium bromide is an anticholinergic drug used to treat colic in horses (0.3 mg/kg IV). N-butylscopolammonium bromide is an antispasmodic drug approved for treatment of colic associated with spasm of the intestine in horses. For other forms of colic, inhibition of intestinal motility may be contraindicated. Another use of N-butylscopolammonium bromide in horses is to relax the large bowel to facilitate rectal examination and colonoscopy.

When used to treat spasmodic colic, within 5–10 minutes of IV injection, spasm of intestinal smooth muscle is relieved and decreased intestinal smooth muscle contraction occurs. The duration is short (20 minutes). Adverse effects from N-butylscopolammonium include other anticholinergic effects such as transient increase in heart rate lasting for approximately 30 minutes. It should not be used in horses with an impaction or in horses with ileus.

Table 46.7 Antidiarrhea drugs and doses

Drug	Dose
Opiates	
Codeine	0.5–1.0 mg/kg, PO, q8–12h
Morphine	0.05–0.1 mg/kg, IM, SC, q8–12h
Diphenoxylate (Lomotil®)	0.1–0.2 mg/kg, PO (dog), q8–12h or 0.05–0.1 mg/kg, PO (cat), q12h
Loperamide (Imodium®)	0.1–0.2 mg/kg, PO, q8–12h
Paregoric	0.05–0.06 mg/kg, PO, q12h
Anticholinergic drugs	
Propantheline (Pro-Banthine®)	0.25–0.5 mg/kg, PO, q8–12h
Aminopentamide (Centrine®)	0.01–0.03 mg/kg, q8–12h or 0.1 mg/cat PO, IM, SC, q8–12h
Diphemanil (Diatha®l)	1.8 mg/kg, IM, q12h

Opioids

Opioids can have both antisecretory and antimotility actions as they act on the μ (mu)-opiate receptors of the GI tract. They decrease propulsive intestinal contractions and increase segmentation (an overall constipating effect) (DeHaven-Hudkins et al., 2008). They also increase the tone of GI sphincters. In addition to affecting motility, opiates have an antisecretory effect and stimulate absorption of fluid, electrolytes, and glucose. Their effects on secretory diarrhea are probably caused by inhibition of calcium influx and decreased calmodulin activity (Hedner and Cassuto, 1987). These drugs can affect small animals and have been documented to inhibit colonic motor activity in horses (Roger et al., 1985; Boscan et al., 2006).

Examples of Drugs

The full range of opioid and opiate drugs are discussed in Chapter 13. The constipating effects of morphine and other opioids are well known. However, it would be irrational to administer morphine repeatedly to animals simply for the antidiarrhea effect. Instead, opioids are used that produce little systemic effect. Two synthetic opioids are known for their specificity of action on the GI tract and their effect on secretory diarrhea. They are primarily active locally on the opiate μ-receptors and they produce GI effects without other systemic side effects. Two such compounds are *diphenoxylate* (Lomotil®) and *loperamide* (Imodium®) (Johnson, 1989). Diphenoxylate is a derivative of meperidine and not commonly used today. Diphenoxylate (Lomotil®) contains 25 μg of atropine per 2.5 mg tablet. The amount of atropine contained in this mixture may contribute to some inhibition of intestinal smooth muscle, but is present in the formulation primarily to discourage abuse by people.

Loperamide is the most often used and is available OTC in capsules (Imodium®) of 2 mg and an oral solution of 0.2 mg/ml (for dosages, see Table 46.7). The typical dose for small animals is 0.1 mg/kg, q 12 h, PO. Paregoric is an older compound (tincture of opium), found in many antidiarrheal products; 5 ml of paregoric corresponds to approximately 2 mg of morphine.

Adverse Effects

Opiates can have potent effects on the GI tract and should be used cautiously. Loperamide is an over-the-counter drug available for people, often administered to animals. These drugs are generally contraindicated in infectious diarrhea because opiates may significantly slow GI transit and increase the absorption of bacterial toxins.

Loperamide ordinarily does not cause central nervous system opiate-related effects because the membrane transporter p-glycoprotein (p-gp) helps to remove this drug from the central nervous system. However, dogs deficient in p-gp (e.g., Collie dogs and other herding breeds) may be prone to toxicity (Mealey, 2004). Consult Chapter 50 for further discussion.

Antimicrobial Therapy for Treatment of Diarrhea

The routine use of antimicrobials to treat diarrhea has been questioned by most gastroenterologists. In most cases of diarrhea in small animals, a bacterial etiology cannot be identified. In large animals diarrhea is often caused by bacteria (enterotoxigenic *E. coli*, for example), but antibiotic therapy may not alter the course of the disease and there is a lack of well-controlled studies to demonstrate efficacy. Nevertheless, oral nonabsorbed antibiotics are sometimes combined with motility modifiers, adsorbents, and intestinal protectants in commercial preparations. Some of these are irrational combinations. Administration of oral antibiotics can actually be a *cause* of diarrhea (Bartlett et al., 2002). More detailed descriptions of the antimicrobials are provided in Chapters 32–37 and 42 of this book. Some examples where antibiotics may be indicated in animals are listed here.

Antibiotic-Responsive Enteropathy in Small Animals

This syndrome has been previously known by different names as *small intestinal bacterial overgrowth (SIBO),* or different forms of antibiotic-responsive intestinal diseases. Now they tend to be grouped together in a larger category of antibiotic-responsive enteropathies.

Escherichia coli *and* Clostridium*:* *Clostridium* spp. is a fastidious gram-positive anaerobic, spore-forming bacillus. Treatments that have been used include antimicrobial treatment and administration of probiotics. When antibiotics are considered, one should administer an oral drug that is active in the GI lumen. The antibiotic administered should have activity against anaerobic bacteria and may include metronidazole, ampicillin, a macrolide, or clindamycin. Vancomycin is used orally in people when resistance to other drugs is suspected.

For intestinal infections caused by *E. coli*, fluoroquinolones are recommended, but other drugs such as amoxicillin, ampicillin, or tetracyclines have been used. *E. coli*-associated granulomatous colitis (seen mostly in Boxer dogs), is treated with fluoroquinolones such as enrofloxacin (see Section Ulcerative colitis in dogs).

One of the drugs used for bacteria overgrowth in people is rifaximin (Xifaxan®). This is an FDA-approved oral antibiotic (200 or 550-mg tablet), that is minimally absorbed systemically (< 0.4%) and excreted in the feces. Because its activity is limited to the lumen of the intestine, it is used for treatment of traveler's diarrhea, hepatic encephalopathy, and irritable bowel syndrome. It has broad-spectrum activity against gram-negative bacteria, gram-positive bacteria, and anaerobes (including *Clostridium* species). Its use in animals has not been reported.

Tylosin-responsive diarrhea: Because some forms of chronic diarrhea in animals have been responsive to the antimicrobial tylosin (Tylan®), it has been characterized as "tylosin-responsive chronic diarrhea in dogs" (Westermarck et al., 2005a, 2005b). This disease, affecting both large and small bowel, is most likely caused by a bacterial pathogen, but the specific etiology has not been identified. *Campylobacter jejuni* and *Clostridium perfringens* have been isolated in some of the affected animals. Tylosin has been effective at improving clinical signs that occur with or without organisms being identified. When administered at 12 mg/kg/day (average dose) response was prompt. Some dogs respond within 24 hours; others respond within 3 days. These benefits appear to be unique to tylosin, because studies by the same investigators showed tylosin at a dose of 20 mg/kg/day was effective, but other drugs (metronidazole, trimethoprim–sulfonamides, doxycycline, or prednisolone) were not.

Sources of tylosin: The powdered form for livestock (Tylan®) has been mixed with the animal's food at a dosage of 40–80 mg/kg/day. One teaspoon contains approximately 3 grams (3,000 mg); therefore, one-quarter teaspoon contains 750 mg – enough for many dogs. Some animals may find the bitter taste unpleasant and refuse their food; therefore, the administration should be tested to identify the method of administration that is best tolerated. Tablets for small animals are available in other countries.

Metronidazole (Flagyl)-responsive diseases: Metronidazole is active against the protozoan, *Giardia*. It is for this use that metronidazole was first administered to treat diarrhea in small animals. Veterinarians discovered that metronidazole also was effective in patients that did not have giardiasis. Bowel inflammation may be caused by metronidazole-sensitive bacteria, which act as an attractant for inflammatory cells. The efficacy of metronidazole may be related to this antibacterial activity. Oral administration of metronidazole at 20 mg/kg to cats decreased the number of anaerobic and aerobic bacteria and altered the indigenous bacterial population (Johnston et al., 2000). There may be an immune-modulatory effect in the intestine (decreased cell-mediated response), but this has not been well characterized. Metronidazole (with and without combination with ampicillin) has been effective for histiocytic ulcerative colitis in dogs (Hostutler et al., 2004). Doses have been as high 60 mg/kg/day for 2 to 4 weeks, but these high doses carry a higher risk of adverse effects; 15 mg/kg twice daily is a safer dose to consider. The dose administered frequently to cats is one-quarter of a 250 mg tablet, two to three times daily (10 to 25 mg/kg). After a response is observed the frequency of administration should be decreased. *One must caution pet owners that when the tablet is broken, the exposed tablet may cause an unpleasant taste for cats.*

Adverse effects from metronidazole are primarily seen as CNS effects, and are discussed in more detail in Chapter 42 of this book. Tremors, seizures, and other CNS disturbances have been documented. CNS problems are caused by inhibition of GABA and are more likely with high doses.

Ronidazole: Ronidazole is from the same chemical group as metronidazole. Compared to metronidazole, it has greater in vitro activity against the protozoa organism *Tritrichomonas foetus*, which causes intestinal infections and diarrhea/lose stools in cats. Ronidazole is one of the few drugs associated with eradication (Gookin et al., 2006). Therefore, it is now the preferred treatment for intestinal infections in cats caused by the organism. It has been administered at a dose of 30 mg/kg once or twice daily for 14 days (once daily is preferred).

Although CNS reactions have been associated with ronidazole treatment in cats, these effects are usually associated with high doses. Because of the long half-life, it may be possible to administer this drug once daily and avoid adverse effects.

Other nitroimidizoles: Tinidazole (Tindamax) is used in people to treat intestinal protozoal infections. The use of tinidazole in animals has only been anecdotal.

***Campylobacter* enteritis:** *Campylobacter jejuni* is a gram-negative microaerophilic curved motile rod. Most infections in animals are self-limiting and not treated. However, the organism may be transmitted to people and this can be a public health concern. This organism is the most common cause of food-borne infectious diarrhea in people. The treatment is aimed primarily at maintaining fluid and electrolyte balance, but if antimicrobials are administered, a macrolide antibiotic is usually the first choice (including azithromycin). Other antimicrobials that may be considered are fluoroquinolones, clindamycin, tetracycline, or chloramphenicol.

Ulcerative colitis in dogs: In some dogs, particularly Boxer dogs, ulcerative colitis has been associated with *Escherichia coli* infection of the colonic mucosa (Mansfield et al., 2009). The invasive bacteria evoke production of inflammatory reactions and produce cytokines responsible for clinical signs. This leads to mucosal infiltration with large numbers of macrophages that induce an inflammatory reaction in the bowel, leading to ulcerative colitis and clinical signs. This differs from the experience with ulcerative colitis in people in which bacteria do not seem to play a role (Danese and Fiocchi, 2011). Successful treatment has been accomplished with oral administration of fluoroquinolones, which are highly active against *E. coli.* One of the regimens includes enrofloxacin at 7 mg/kg, once a day, for a duration of 9 weeks, but it is possible that a shorter course of treatment also would be effective.

Salmonella: The primary goal when treating *Salmonella* is to maintain fluid balance and prevent electrolyte losses. The patients should be isolated to prevent spreading of infection and strict containment procedures should be instituted in the hospital. Antibiotics are discouraged unless absolutely necessary for patients with *Salmonella* because antibiotic therapy may prolong shedding. In horses, if there is fever and neutropenia, intravenous gentamicin should be considered. Other drug choices include the following: fluoroquinolones, chloramphenicol or florfenicol (depending on the species), ampicillin or amoxicillin or amoxicillin–clavulanate, trimethoprim–sulfonamide, or a cephalosporin (the activity against *Salmonella* is highest with third-generation cephalosporins).

Antibiotic Treatment in Calves and Pigs

Use of antibiotics to treat diarrhea is common in young ruminants and pigs. A review of the relevant literature was summarized by Constable (2004). This author points out that the following antimicrobials are approved for treatment of calf diarrhea: amoxicillin, chlortetracycline, neomycin, oxytetracycline, streptomycin, sulfachloropyridazine, sulfamethazine, and tetracycline, *all* administered orally. Some of these drugs were approved many years ago – approximately 50 years ago in some cases – before evidence was required for approval. Of all these drugs listed, only amoxicillin has been shown to be effective in well-controlled studies. Other drugs may be effective, (fluoroquinolones, chloramphenicol, nitrofurazone) but it is a violation of federal regulations to administer these drug for this indication in calves. If bacteremia develops as a complication of bacterial diarrhea in calves, systemic therapy is needed. Drugs most often given systemically (IM, SC, or IV) for this indication include ceftiofur and ampicillin.

In baby pigs, there are oral formulations of aminoglycosides (e.g., gentamicin – *Garacin Pig Pump*) to be administered orally to baby pigs 1–3 days of age. Other forms of gentamicin are intended to be added to drinking water to treat diarrhea in weaned pigs or for swine dysentery (1–3 day treatment). Other aminoglycosides (e.g., neomycin and amikacin) also have been administered orally to pigs for diarrhea.

Antibiotic Treatment for Diarrhea in Foals

Diarrhea in foals is common. Normal nursing can maintain hydration in mild cases. But in more severe cases, fluid and electrolyte therapy is needed to maintain hydration. For infections caused by *Clostridium* spp., metronidazole has been used. For treatment of *Salmonella* (if indicated) aminoglycosides and/or cephalosporins (systemically) can be used, especially if systemic treatment is indicated with signs of sepsis. In horses 3–6 months of age, a disease characterized as *proliferative enteropathy* is caused by the organism *Lawsonia intracellularis*, so-named because it is an obligate intracellular pathogen. Affected animals show signs of lethargy, anorexia, depression, weight loss, colic, diarrhea, and hypoproteinemia. Treatment in horses has included erythromycin, azithromycin, chloramphenicol, clarithromycin, and doxycycline. Tetracyclines (doxycycline or oxytetracycline) are preferred. In pigs *Lawsonia intracellularis* also causes intestinal disease. The recommended treatment is a tetracycline and tylosin, added to feed.

Drugs for Treatment of Inflammatory Intestinal Diseases

Intestinal inflammatory diseases cover a wide range of etiologies grouped together because many have similar clinical signs. Among the diseases that may be included in this group are those caused by parasites, bacteria, food hypersensitivity, or immune-mediated diseases. Inflammatory bowel disease (IBD) may involve the small intestine or large intestine. There are similarities to intestinal diseases in people, which were reviewed by Hanauer (1996).

Inflammatory bowel disease (IBD) is a collective term that describes a group of disorders characterized by persistent or recurrent signs and histological evidence of inflammation that may involve the small or large intestine. Inflammation may be characterized by the cells infiltrating the mucosa (lymphocytic, plasmacytic, eosinophilic, neutrophilic). When there are bacterial causes, IBD may be the result of overexuberant inflammatory response to a bacteria invading the intestinal mucosa. In the large intestine, the disease is often referred to simply as colitis but also may be associated with many etiologies. Chronic colitis may be lymphocytic, plasmacytic (most common), eosinophilic, or granulomatous, which is associated with macrophages and inflammatory cells.

Initial therapy for inflammatory intestinal disease is aimed at managing the underlying cause. Therefore, antiparasitic therapy and dietary therapy are usually pursued initially. Antiparasitic drugs are discussed in Chapters 39–42. Dietary management and probiotics are also used for treatment. When these treatments have failed, or a specific etiology has not been identified, drug therapy consisting of antiinflammatory drugs is used, or combined with other treatments.

Sulfasalazine (Azulfidine®)

Sulfasalazine is used as an initial drug therapy for treatment of colitis. It is not as effective for inflammatory diseases of the small intestine. Sulfasalazine is a combination of sulfapyridine and 5-aminosalicylic acid (mesalamine) joined by an azo bond. The bond is broken by bacteria in the colon to release the two drugs (Figure 46.4). The sulfonamide component is absorbed into the circulation while the salicylic acid component remains active in the GI tract. Less than half of the salicylate component is absorbed systemically.

Clinical Use

Many veterinarians consider sulfasalazine to be the drug of choice for the initial treatment of ulcerative or idiopathic colitis, or plasmacytic–lymphocytic colitis after dietary therapy has been attempted. Clinical efficacy is attributed to a local antiinflammatory action from the salicylate component. There is also evidence for antilipooxygenase (LOX) activity, decreased IL-1, decreased prostaglandin synthesis, and oxygen radical scavenging activity.

Dosage recommendations start at 10–25 mg/kg q 8 h, PO, but have been as high as 40 mg/kg, two to three times per day. The dose is then reduced after there is an initial response to treatment.

Adverse Effects

The salicylate component is absorbed only minimally. The sulfonamide component is absorbed and can produce adverse effects in some animals, such as keratoconjunctivitis sicca in dogs (Morgan and Bachrach, 1982). This drug cannot be used in patients that have allergic reactions to sulfonamides.

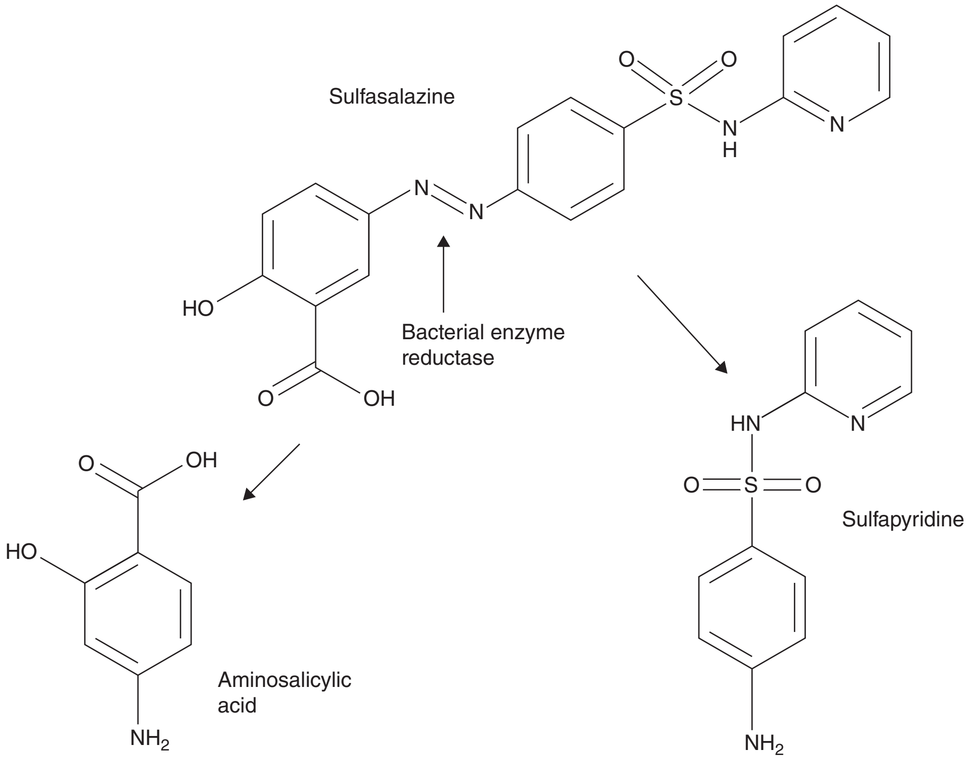

Figure 46.4 Sulfasalazine is a combination of sulfapyridine and 5-aminosalicylic acid (mesalamine) joined by an azo bond. The bond is broken by bacteria in the colon to release the two drugs. The sulfonamide component is absorbed, but the salicylic acid component remains active in the GI tract.

Other Sources of 5-Aminosalicylic Acid (Mesalamine)

In people, the adverse effects associated with sulfasalazine therapy are primarily due to the sulfonamide component; therefore, drugs have been formulated to contain mesalamine (5-aminosalicylic acid) without the sulfonamide. These formulations are listed in Table 46.8. Some formulations are designed to release the active drug at the distal portion of the intestine or colon because generally the pH is higher in these regions of the intestine.

Anticholinergic Drugs (Antimuscarinic Drugs)

As discussed previously, anticholinergic drugs (atropine-like drugs) inhibit smooth muscle and glandular secretions of the GI tract (also discussed in Chapter 8). Anticholinergic drugs occasionally have been used for the treatment of colitis. However, colitis is not ordinarily associated with hypermotility and the rationale of anticholinergic drugs should be questioned. Patients with a hypermotile or spastic bowel may have a limited benefit from these drugs.

Anticholinergic drugs also may have a role for reducing straining during the postoperative management of rectal and/or anal surgical procedures. A common drug for these indications is propantheline (Pro-Banthine®) at a dosage of 0.25 mg/kg, orally, two or three times daily.

Table 46.8 Mesalamine (5-aminosalicylic acid) formulations

Asacol®: Asacol is a tablet coated with an acrylic-based resin. The resin dissolves at a pH of 7.0 and is designed to release 5-aminosalicylic acid in the colon. It is available as a 400 mg tablet.

Mesasal®: Mesasal is a tablet coated with an acrylic-based resin that dissolves at a pH of >6.0. It is designed to release 5-aminosalicylic acid in the terminal ileum and colon. Approximately 35% of the salicylate is absorbed systemically. It is available in 250 and 500 mg tablets. The dose in people is 1 to 1.5 g/day.

Olsalazine sodium (Dipentum®): Olsalazine is a dimer of 2 molecules of 5-aminosalicylic acid linked by an azo bond. It is used in people who cannot tolerate sulfasalazine. Only 2% of the salicylate from this compound is absorbed systemically. It is available in 500 mg tablets. The most common adverse effect in people from this preparation has been a watery diarrhea.

Pentasa®: This formulation contains microgranules of mesalamine coated with ethyl cellulose, which releases 5-aminosalicylic acid into the small and large intestine gradually, regardless of pH.

Glucocorticoids

The effects of glucocorticoids for treating inflammatory bowel diseases are probably related to their antiinflammatory and immunosuppressive ability (Dillon, 1989).

It is believed that colitis is the result of autoantibodies and T-lymphocytes directed against the colonic epithelial cells. Corticosteroids, via their ability to suppress cytokine synthesis, leukocyte migration, and lymphocyte activation suppress the activity responsible for inflammatory bowel disease clinical signs. Glucocorticoids have been used when a biopsy suggests eosinophilic colitis or lymphocytic–plasmacytic colitis (Washabau and Holt, 2005; Leib et al., 1989). They are often employed when other forms of therapy (including dietary) have failed. The pharmacology of the corticosteroids is discussed in more detail in Chapter 29, and with immunosuppressive agents in Chapter 45.

Clinical Use and Dosages

The dose of prednisolone initially is in the immunosuppressive range of 2 to 4 mg/kg per day in divided doses for dogs and cats. Although there are no comparisons between prednisone and prednisolone, it is advised to use prednisolone. Prednisone is an inactive drug that relies on the conversion to the active drug prednisolone. If a local (topical) effect is desired from an oral dose, prednisolone is preferred over prednisone. Moreover, there is evidence in cats that some animals do not convert prednisone to the active drug.

After initial response is observed, the doses are tapered to approximately 1 mg/kg every other day if there is a positive treatment response. Prednisolone may be administered with azathioprine (see section Azathioprine). The magnitude of the dosage depends on the severity of the disease. Cats with severe inflammatory bowel disease have required prednisolone dosages as high as 4 mg/kg/day. Injections of corticosteroids (for example, methylprednisolone acetate DepoMedrol® at 20 mg/cat) for the control of inflammatory bowel disease has not been as successful as oral therapy. *Veterinarians should be aware that some animals develop diarrhea when treated with glucocorticoid therapy.*

Local Treatment with Budesonide (Entocort EC)

Budesonide is a locally acting corticosteroid. It has been used in people, but there also has been used in dogs and cats. Budesonide granules are contained in an ethylcellulose matrix that is coated with methacrylic acid polymer. This coating does not release the drug until the pH >5.5. In the proximal intestine the pH is low and it gradually increases in the distal intestine to attain a pH above 7. Therefore, the drug is not released until it reaches the distal GI tract. If a portion of the drug is absorbed, 80–90% is inactivated by first-pass metabolism. Therefore, systemic glucocorticoid effects are minimized. In humans it has been as effective as other drugs for treatment of Crohn's disease. It is available in a 3-mg capsule and is used in people at a dose of 9 mg/day.

Use of budesonide in animals: The experience with budesonide in dogs and cats has been limited, but provide some evidence of a beneficial effect. The intestinal pH is generally higher in small animals than people and a quicker release of the active drug is possible compared to people. Although systemic absorption is small, some may occur because there was a decreased response to ACTH after 30-day treatment to dogs at 3 mg/m^2. Other adverse effects were not observed (Tumulty et al., 2004).

Immunosuppressive Drugs

Immunosuppressive drugs also have been used to manage some forms of inflammatory bowel diseases. The most commonly used immunosuppressive drug for intestinal disease is azathioprine. The use of other drugs, such as cyclosporine, has been more limited.

Azathioprine

Azathioprine (discussed in Chapter 45) is metabolized to active metabolites that inhibit activated lymphocytes thereby suppressing lymphocyte response. Azathioprine (Imuran®) has been used at dosages of 2 mg/kg once daily and 40 mg/m^2 once daily in dogs with severe inflammatory bowel disease. The dose may be decreased to 0.5 mg/kg every other day if there is a positive initial response. Azathioprine has caused other GI problems during therapy (e.g., diarrhea during the initial therapy and liver injury with longer use); therefore, careful monitoring during treatment is recommended. Cats are more sensitive to the adverse effects than dogs and other drugs are usually administered to cats (e.g., chlorambucil, see Section Chlorambucil).

Chlorambucil

Chlorambucil, an alkylating agent, also is used in combination with prednisolone for treatment of chronic enteropathy and inflammatory bowel disease. The dose administered has been 4–6 mg/m^2, oral every 24 hours. If there is a positive response, the dose and frequency can be reduced. In one study, the combination of chlorambucil–prednisolone was more effective than the combination of azathioprine–prednisolone for treating chronic enteropathy and protein-losing enteropathy in dogs (Dandrieux et al., 2013).

N-3 Fatty Acids For Colitis

In people, omega-fatty acids (n-3 fatty acids) such as eicosapentanoic acid are beneficial for the treatment of colitis. These compounds are available in veterinary medicine in products such as DermCaps®, Pet-Derm®, and others for the purpose of treating pruritic skin disease. In studies performed in people with ulcerative colitis, supplementation for 4 months with omega fatty acids reduced leukotriene levels in the colon, and

Table 46.9 Use of laxatives and cathartics in veterinary medicine

Promotes the elimination of a soft-formed stool
Increases passage of intestinal contents to relieve an impaction (equine)
Cleanses bowel prior to radiography or endoscopy
Promotes the elimination of a toxin from the intestine
Softens stools following intestinal or anal surgery (decreases straining)

improved clinical signs. The clinical efficacy of these compounds for treating small animals with colitis has not been reported.

Cyclosporine

Cyclosporine (Neoral®, Atopic®) has been used to treat perianal fistulas, which are a component of ulcerative colitis (pharmacology of cyclosporine is discussed in Chapter 45). The treatment for this disease has been very successful. In addition, cyclosporine has been used to treat diarrhea caused by inflammatory bowel disease (Allenspach et al., 2006). At a dose of 5 mg/kg PO, q 24 h, ×10 weeks there was improvement in 78% of dogs. The success is attributed to the ability of cyclosporine to suppress T-cell mediated activity in the bowel, and to suppress inflammatory cytokines.

Laxatives and Cathartics

Laxatives and cathartics are drugs that increase the motility of bowel and change the character of the stool. Uses of these drugs are listed in Table 46.9. These drugs promote the elimination of soft-formed stool or increase fluid content of stool, which increases the bulk. Laxatives and cathartics can be divided into (i) bulk-forming laxatives, (ii) stool softeners, (iii) lubricants, (iv) saline hyperosmotic agents, and (v) stimulants. They also may be categorized by their onset of action: the osmotic (saline) laxatives act in 1–3 hours; the direct stimulants act in 6–8 hours; the bulk laxatives and surfactants act in 1–3 days.

Stimulant (Irritant) Laxatives

The exact mechanism of action for this group of laxatives is uncertain, but they appear to cause electrolyte loss by inhibiting Na^+/K^+-ATPase in the intestine and increasing electrolyte loss through intestinal tight junctions. These drugs are among the most rapidly acting of the laxatives, with action within 6–8 hours. They can have potent effects and excessive fluid and electrolyte loss can result from overdoses. Adverse effects can result from damage to enterocytes from chronic use and abuse. Some of the agents available include:

diphenylmethane: use is not documented in veterinary medicine;
phenolphthalein: this was once an ingredient found in over-the-counter laxative preparations such as ExLax®, but is no longer available (other natural ingredients are now used in ExLax®);
anthraquinone: these are glycoside derivatives found in bisacodyl (Dulcolax®), senna (Senokot®), and cascara sagrada (Nature's Remedy®).

Hyperosmotic Cathartics (Saline Cathartics)

The saline cathartics are nonabsorbed electrolytes that draw fluid into the bowel via osmosis. These are the most rapidly acting of the cathartics, with onset of action in 1–3 hours. The fluid content of the stool increases, which causes intestinal distention and promotes increased normal peristalsis. These have been some of the most commonly used cathartics in veterinary medicine. Most often they are dissolved in an aqueous solution (water) and administered via gastric gavage (stomach tube). These drugs have been used to prepare animals for an endoscopic procedure (*bowel cleansing)* or for cathartic treatment of poisoning. They are relatively safe drugs, but overdoses can cause fluid loss in a patient. Examples of these drugs are shown in Table 46.10.

Hydrophilic Colloids ("Bulk Laxatives")

These agents are mostly natural products and dietary plant fibers. They are composed of nonabsorbed synthetic or natural polysaccharide and cellulose derivatives. These fibers are resistant to digestion and attract water into the intestine. By imbibing water, they increase the

Table 46.10 Saline cathartics

Sodium sulfate **(Glauber's salt)**
Magnesium salts such as magnesium sulfate (Epsom Salts), magnesium hydroxide (Milk of Magnesia), and magnesium citrate (Citro-Mag®)
Nonabsorbed sugars: Lactulose, Mannitol, Polyethylene glycol (PEG)
Lactulose also is used to treat hepatic encephalopathy. Its action lowers the bowel pH and decreases ammonia absorption by converting to NH^{+3}. The ionized form of the compound is less absorbed systemically.
Combination products: Golytely is a strong osmotic cathartic that is a combination of sodium sulfate, potassium chloride, sodium chloride, sodium bicarbonate, and polyethylene glycol (PEG 3350). The dose is 250 ml to one liter per animal (depending on the size) and has a rapid onset of action. The most common use of this product is for bowel cleansing prior to an endoscopic procedure.

Table 46.11 Bulk laxatives

Carboxymethylcellulose
Methylcellulose
Psyllium (Metamucil) powder
Prunes and wheat bran and other attempts to increase “fiber” in the diet
For cats, canned pumpkin is a source of fiber that most cats eat readily

mass of nondigestible material in bowel and motility is increased through the stimulation of mechanoreceptors. They are more slowly acting than other drugs with an onset of action of 24 hours, or longer. They are relatively safe drugs with few side effects. Examples are included in Table 46.11.

Lubricant Laxatives (Mineral Oil and Liquid Petrolatum)

The lubricants act by coating the surface of the stool with a water-immiscible film and increasing the water content of the stool. They also produce a lubricant action to ease passage of the stool. Lubricant laxatives usually contain mineral oil (liquid petrolatum) or white petrolatum. Many of the nonprescription products contain white petrolatum (Vaseline®) as their ingredient. Administration of glycerin also has been used as a lubricant laxative. The lubricant laxatives are relatively safe because they are absorbed from the GI tract only to a small extent. The worst adverse effect is that they may possibly elicit a foreign body reaction. Chronic use may decrease the intestinal absorption of fat-soluble vitamins.

Use in large animals: These drugs, particularly mineral oil, are popular for several nonspecific GI problems in horses and cattle.

Use in small animals: Products such as Laxatone®, Felaxin®, and Kat-a-Lax® are promoted for increasing the passage of trichobezoars (hair balls) in cats. These products contain white petrolatum (Vaseline) as their active ingredient with additional flavorings.

Stool Softeners (Surfactants)

These drugs act to decrease surface tension and allow more water to accumulate in the stool. Their onset of action is usually 24–48 hours. They are relatively safe, except cramping pains are reported in people if they ingest high dosages.

Docusates: Dioctyl sodium sulfosuccinate (DSS, Colace®) and dioctyl calcium sulfosuccinate (Surfak®, Doxidan®). Also known as docusate sodium and docusate calcium, these compounds are used when there is a need to soften the stool. Efficacy in animals has not been tested.

Bile acids: Bile acids include dehydrocholic acid and ursodeoxycholic acid (Ursodiol, Actigall). Bile acids can produce both a choleretic (increase bile flow) and laxative effect. Ursodeoxycholic acid is better known by most veterinarians for other uses. Although listed with the laxatives, most of the use of ursodeoxycholic acid (Ursodiol®), in veterinary medicine is for the management of liver disease in animals, rather than for its laxative action. Ursodeoxycholic acid has an important effect in slowing progression, or improving, liver disease (Lindor, 2007). Because ursodiol is a water-soluble bile acid, administration may alter the circulating pool of bile acids to replace some of the more toxic, hydrophobic bile acids from accumulating in animals with liver disease.

Castor oil: Castor oil is hydrolyzed in the bowel to release ricinoleic acid, which causes an increased secretion of water in the small intestine.

Acknowledgment

The author acknowledges the important contribution of Dr. Katie Tolbert, University of Tennessee to the section on proton pump inhibitors.

Dermatopharmacology: Drugs Acting Locally on the Skin

Jim E. Riviere and Rosanna Marsella

A large number of cases seen in the everyday practice of small- and large-animal veterinary medicine involve lesions of the skin or its appendages. This chapter reviews the salient features of the general anatomy, histology, and biochemistry of skin relevant to the treatment of dermatological disease; acquaints the practitioner with the features of percutaneous drug absorption relevant to the treatment of skin disease; and discusses the categories of pharmacological preparations available on the veterinary market to treat skin diseases in domestic animals. The specific drugs used to treat skin diseases are well covered in other chapters of this text. Chapters that should be consulted for application to skin disease include those on antimicrobials, analgesics, and antiinflammatory drugs; antipruretics and antihistamines; glucocorticoids; immunosuppressives (cyclosporine); and ectoparasiticides.

Only in the last few decades have scientists begun to understand how the skin functions in normal and diseased states, to understand the skin's barrier function in terms of water loss and drug delivery, and that attempts have been made to improve the delivery of pharmaceutical agents through the skin by temporarily adjusting that barrier to deliver the drug. In order to successfully minimize the skin's ability to block the absorption of drugs to treat dermatological disease in domestic animals, it is imperative to understand the normal functional anatomy and biochemistry of the skin. In veterinary medicine, transdermal delivery is widely employed when pesticides are applied monthly to a single area of skin for the control of fleas and ticks over the entire body. Transdermal fentanyl patches are also widely used for postsurgical analgesia. This topical port of drug delivery will see increased use for other therapeutic indications. However, most drugs applied to the skin are not intended to be absorbed systemically but are used to elicit a local therapeutic effect in the treated skin.

The characteristic that separates dermatological therapy from other components of veterinary pharmacology is this use of topical dosage formulations to treat surface conditions or to target the underlying skin. The drugs are not different from those used in other diseases, but they are different in the vehicles employed and mode of administration. A full understanding of the biological factors that modulate absorption and of the pharmaceutical composition of dermatological formulations (e.g., vehicles) is essential to a proper understanding of dermatopharmacology. The same principles also apply to the absorption of topical transdermal preparations such as pour-on ectoparasiticides and analgesics such as transdermal fentanyl gels or patches. It must be stressed that the drugs incorporated into these formulations are the same as those used to treat diseases of other systems and thus, their descriptions will not be repeated in this chapter.

Anatomy and Histology

The skin is the largest organ of the body, with the integument accounting for 24% of the overall body weight in the puppy and 12% in the adult dog (Pavletic, 1991). The skin has the function of protecting the internal organs of the body from extremes in temperature fluctuations, allergens, pollutants, toxic chemicals, and organisms such as bacteria, fungi, parasites, and viruses found ubiquitously in the environment.

The skin of domestic animals is quite similar in gross and histological morphology across species lines and is usually thickest over the head, dorsum of the neck, back, and sacrum and on the plantar and palmar surfaces of the feet. It is thinner on the ventral abdomen, the medial surfaces of the limbs, and the inner pinnae, and thinnest over the scrotum of male animals and the earlobe of the human. Perforating the skin are several types of appendages (depending on the species), such as hair follicles, sebaceous and sweat glands, spines, quills, scales, spurs, horns, claws, nails, and hooves (Montagna, 1967). The specific anatomy of skin and hair has been reviewed extensively elsewhere (Monteiro-Riviere, 2006; Blackburn, 1965; Lloyd et al., 1979a, 1979b; Sar and Calhoun, 1966; Kozlowski and Calhoun, 1969; Strickland

and Calhoun, 1963; Talukdar et al., 1972; Pavletic, 1991; Montagna, 1967; Amakiri, 1973).

The Epidermis

On the histological level, the skin can be divided into two distinct units: the epidermis and the dermis. The epidermis consists of stratified squamous keratinized epithelium that undergoes a programmed proliferation and differentiation that will eventually result in the formation of the major barrier to drug penetration: the stratum corneum. Two primary cell types exist in the epidermis: those of keratinocyte origin and those of nonkeratinocyte origin.

Five distinct layers of keratinocytes can be present in the epidermis, as shown in Figure 47.1. Listed from the deepest layer of the epidermis to the most superficial, they are (i) stratum basale (basal layer), (ii) stratum spinosum (prickle layer), (iii) stratum granulosum (granular layer), (iv) stratum lucidum (clear layer), and (v) the stratum corneum (horny layer). Each cell layer has its point of origin at the stratum basale. The stratum basale is a single layer of cuboidal or columnar cells that rest on the basal lamina. These cells are attached to the basal lamina by hemidesmasomes, and to each other and to the cells of the stratum spinosum by desmasomes. The stratum basale cells continuously divide, with some remaining as basal cells and others beginning to move more superficially and mature by changing their intracellular content through the process called *keratinization*. This viable and dividing epidermal cell layer is the target for transformation into cancerous cells.

The next more superficial layer next to the stratum basale, the stratum spinosum, is composed of irregularly shaped polyhedral cells that make up much of the bulk thickness of the epidermis. The next layer composes the stratum granulosum, which consists of several layers of cells that begin to flatten horizontally. Of primary interest are the lamellated granules within these cells, which contain polar phospholipids, such as glycosphingolipids and free steroids, and numerous hydrolytic enzymes, including acid phosphatase, proteases, lipases,

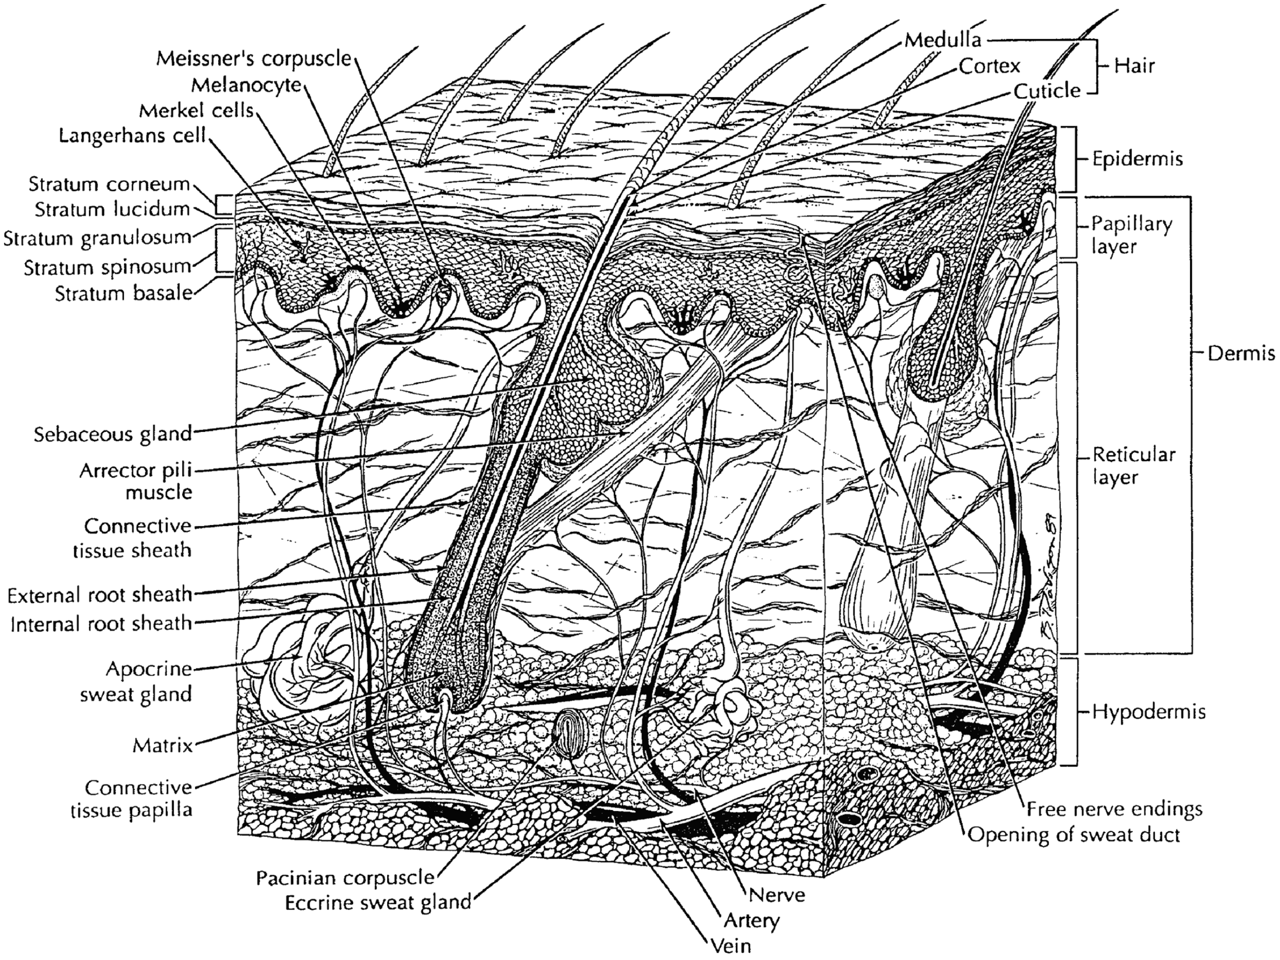

Figure 47.1 A schematic view of the epidermis and dermis of the skin. Source: Monteiro-Riviere, 1991. Reproduced with permission of Taylor & Francis Group LLC.

and glycosidases. As these intracellular products accumulate, these cells will exocytose their intracellular products and fill in the intercellular spaces, eventually forming the extracellular lipid matrix of the stratum corneum that forms the penetration barrier of the stratum corneum. As these epidermal cells continue their migration, they form the stratum lucidum, a translucent line of cells found only in areas having very thick skin, such as plantar and palmar surfaces (footpads) and the planum nasale. These cells are translucent because both nuclei and cytoplasmic organelles are missing (Monteiro-Riviere, 1991, 2006; Idsen, 1975; Montagna, 1967).

The stratum corneum is the final and most superficial layer of the epidermis and is its most important when considering the feasibility of topical drug therapy since it is the primary barrier to percutaneous absorption. In addition to the barrier function for xenobiotics trying to enter the body from the environment, the stratum corneum also provides a barrier to insensible water loss, an evolutionary adaptation that allows terrestrial animals to exist in a nonaquatic environment. In fact, most veterinary dermatological vehicles are targeted at this action. This layer consists of several dead layers of cells, organized into vertical columns in a tetrakaidecahedral (14-sided) configuration, the thickness of which varies depending on location (Monteiro-Riviere, 1991). This particular cell shape provides a minimal surface-to-volume ratio and also minimizes systemic water loss through the skin (transepidermal water loss). Each cell is ingrained in the lipid matrix produced by the lamellated granules when the cells were still in the stratum granulosum layer. These dead cells are also surrounded by a thick plasma membrane with a submembranous layer of involucrin, also produced earlier in development. With intracellular and intercellular barriers firmly in place, the stratum corneum has the ability to constrain the passage of unwanted chemicals and toxins from the environment. Unfortunately, the stratum corneum does not discriminate between these unwanted substances and the pharmaceuticals the veterinarian may wish to penetrate the skin for topical drug therapy for the treatment of dermatological disease.

Melanocytes are cells located in the basal layer of the epidermis and contain dark cytoplasmic granules called melanosomes. These cells impart color to the skin, the color and intensity determined by the number, size, distribution, and degree of melanization of the melanosomes. Merkel cells are also located in the basal region of the epidermis and are thought to function as slow-adapting mechanoreceptors for touch. Langerhans cells are located in the stratum spinosum but can also be present in dermal lymph vessels, lymph nodes, and dermis. The Langerhans cells' primary function is to present antigen to lymphocytes; they may also be the initial receptors for cutaneous immune responses.

The Dermis

The dermis is composed of connective tissue, consisting of collagen, elastin, and reticular fibers dispersed in an amorphous ground substance, and can be divided into two rather poorly demarcated areas. The papillary layer consists of loose connective tissue and connects the epidermis (stratum basale/basal lamina) to the deeper reticular layer of the dermis. The reticular layer consists of dense connective tissue connected to the hypodermis, which is composed mostly of fat.

Dispersed throughout both layers of the dermis is a network of arterial and venous blood vessels needed to nourish the cells of the epidermis and dermis as well as take part in the last stages of the percutaneous absorption of compounds. Lymph vessels, nerves, apocrine and eccrine sweat glands, sebaceous glands, Pacinian (pressoreceptor), Meissner's (touch receptor), and Ruffini (mechanical receptor) corpuscles, hair follicles, and smooth muscles (arrector pili) are the other major structures found in the dermis. Two types of arteries, musculocutaneous and direct cutaneous, supply the needed nutrients to the epidermis. Direct cutaneous arteries run parallel to the skin, directly supplying the skin with blood, while musculocutaneous arteries supply both the skin and underlying musculature and run perpendicular to the skin. Cutaneous blood supply by each type of artery varies with species and location. Cutaneous blood flow rates may be one of the factors affecting the passive percutaneous absorption of chemicals. Table 47.1 clearly demonstrates this by comparing laser Doppler cutaneous blood flow parameters in nine species of domestic animals (Monteiro-Riviere et al., 1990).

Species Differences

As a general rule, skin structure and function are similar across species lines. However, some minor differences are apparent.

Avian integument possesses the most profound differences in skin morphology from other domestic species. The four layers of the epidermis are, from the deepest to the most superficial, the stratum basale, the stratum intermedium (stratum spinosum), the stratum transitivum (stratum granulosum), and the stratum corneum (stratum germinativum). Unlike mammals, avians possess no skin glands (Monteiro-Riviere, 2006). The skin of aquatic mammals has a very thick stratum corneum resembling parakeratosis and there is no stratum granulosum (Montagna, 1967).

Pig skin is similar histologically to human skin (Monteiro-Riviere and Stromberg, 1985) and has been used experimentally to reliably predict the percutaneous absorption of chemicals in humans (Riviere, 2006).

With respect to cutaneous circulation, musculocutaneous arteries are the primary vascular supply to the skin of humans, apes, and swine. Loose-skinned animals (canines and felines) lack musculocutaneous arteries; all vessels involved in cutaneous circulation travel parallel to the skin (Pavletic, 1991). Studies of piroxicam (a nonsteroidal antiinflammatory drug) in pigs suggest that the type of cutaneous circulation may affect the local tissue concentrations of topically applied drug (Monteiro-Riviere et al., 1993). Little work has been done directly comparing the absorption of drugs and topical pesticides across veterinary species (Riviere and Papich, 2001).

Biochemistry

Energy Production and Utilization

The skin, specifically the epidermis, is mostly an anaerobic organ. The absence of capillaries directly feeding oxygen to the epidermal cells makes the epidermal cells relatively oxygen poor in the normal state when compared to other tissues with a more direct blood supply. Due to this low oxygen tension, the epidermis produces 70–80% of its total energy requirements (adenosine triphosphate) through the anaerobic metabolic pathway (glycolysis), with lactic acid being the end product of glucose utilization. The epidermal cells, the most active of which are those in the single layer of the stratum basale, are the primary cells involved in this energy production, with the lactic acid end product passively diffusing into the dermis and then into the blood vasculature, eventually recycled by the liver back into glucose. Although the glycolytic pathway produces most of the energy requirements of the epidermis, other energy pathways (tricarboxylic acid cycle and pentose phosphate shunt) are also utilized to lesser degrees in some phases of epidermal growth (Freinkel, 1983).

Some topically applied drugs may have an effect on energy production pathways within the epidermis. One study (Spoo et al., 1993) showed that in vitro weanling porcine skin flaps had large increases in epidermal cell glucose utilization when the skin was dosed with benzoyl peroxide. In addition to drugs, vehicles (discussed in more detail in Section Topical Vehicles) may also have similar effects.

Drug Biotransformation

The stratum corneum is the primary line of defense to prevent percutaneous absorption of drugs. However, any drug passing through the stratum corneum may face a metabolic, rather than a physical, barrier. The skin has a remarkable ability to metabolize xenobiotics. These metabolic reactions consist mainly of oxidation, reduction, hydrolysis, and the phase I and II conjugation reactions. Enzymes present within the extracellular lipid matrix include acid lipase, phospholipase A, sphingomyelinase, glycosidases, acid phosphatases, cathepsins, and carboxypeptidases (Elias, 1992). Some of these reactions are major pathways for the metabolism of topical steroids as well as other drugs such as norepinephrine, benzoyl peroxide, and benzo(a)pyrene.

Skin has been shown to metabolize organophosphate parasiticides. When parathion is topically applied to the skin and penetration through the stratum corneum occurs, it undergoes significant metabolism within the epidermis to the bioactive metabolite paraoxon and/or *p*-nitro phenol, both of which will enter the systemic circulation to possibly affect other organ systems (Riviere and Chang, 1992). Additional studies have demonstrated the metabolic capabilities of skin when topically exposed to caffeine, testosterone, butylated hydroxytoluene, salicylic acid, norepinephrine, benzo(a)pyrene, and benzoyl peroxide – to name only a few – in many species of laboratory animals, as well as in human skin. Benzoyl peroxide, a popular veterinary drug used as a keratolytic and degreasing agent, is metabolized almost 100% to benzoic acid within the epidermis. In addition, the cytochrome P450 enzyme system, most commonly associated with the liver, is present and is inducible in skin (depending on the compound that was applied topically) and is the pathway that is responsible for the conversion of parathion into paraoxon in porcine skin (Riviere and Chang, 1992; Mukhtar, 1992; Bashir and Maibach, 2005). Glutathione-*S*-transferase, aryl hydrocarbon hydroxylase, and 7-ethoxycoumarin have also been demonstrated to exist in rat and mice epidermal cell homogenates (Raza et al., 1992). These studies all show that the skin has formidable metabolic functions as well as the traditional barrier functions.

Lipid Metabolism

In addition to its metabolic activities, skin also has a marked ability to synthesize lipid, which is used to construct the extracellular epidermal barrier. Epidermal cells manufacture a variety of neutral lipids, ceramides, glycosylceramides, gangliosides, sterol esters, fatty acids, alkanes, and phospholipids, which are largely found in the extracellular barrier of the stratum corneum. Some of these lipids tend to be site specific, with phospholipids and sterols residing mostly in the basal cell layers and some sterols and neutral lipids occupying the upper regions of the epidermis, mainly the stratum corneum. The effects on percutaneous absorption by the intercellular lipid structure have been discussed in greater detail elsewhere (Wertz, 1992; Potts and Francoeur, 1992; Hadgraft et al., 1992; Swartzendruber, 1992; Elias and Feingold, 1992; Monteiro-Riviere et al., 2001). It is now accepted that this complex intercellular lipid matrix provides the primary barrier to drug penetration. It is important to realize that in some skin disease states, the overall production of lipids by the epidermal cells may be altered due to altered intracellular metabolism, subsequently followed by some alterations in the percutaneous absorption patterns of many drugs. Alterations in the epidermal cells' plasma membrane (primarily composed of lipid) – whether due directly to a drug(s), by the vehicle a drug was delivered in, or due to a disease process – may incite inflammatory reactions due to the release of inflammatory mediators (eicosanoids) from the epidermal cells or from the underlying cutaneous vasculature.

Eicosanoids are a group of biologically active compounds derived enzymatically from eicosatetraenoic acid (arachidonic acid). Prostaglandins, leukotrienes, thromboxanes, and hydroxyeicosatetraenoic acids can be produced in minute quantities from arachidonic acid and have powerful proinflammatory effects on skin and the surrounding tissues. Eicosanoids are found in nearly every tissue in the mammalian body (Spannhake et al., 1981; Dunn and Hood, 1977; Goldyne, 1986), with some cells specializing in a certain type of eicosanoid. Skin produces several prostaglandins, including PGE_2, $PGF_{2\alpha}$, and PGI_2, as well as the lipoxygenase product leukotriene B_4.

PGE_2 induces vasodilation by elevating cyclic adenosine monophosphate in vascular smooth muscle cells, while $PGF_{2\alpha}$ causes vasoconstriction of the cutaneous vasculature by elevating cyclic guanosine monophosphate levels in vascular smooth muscle cells. In contrast to PGE_2, increased $PGF_{2\alpha}$ concentrations in skin enhance the leukocytes' response to chemotactic stimuli. $PGF_{2\alpha}$ has many effects on organs other than the skin, most notably in the reproductive tract of both humans and domestic animals. PGI_2 is a potent vasodilator produced mainly by vascular endothelial cells; it also inhibits vascular platelet aggregation. PGI_2 can be released from skin in response to some vehicles – namely, alcohols such as methanol, ethanol, and 2-propanol (Landolfi and Steiner, 1984; Karanian et al., 1985). Cutaneous vasodilation has been observed in humans orally consuming alcohol (ethanol), presumably due to release of PGI_2 from vascular endothelial cells in contact with the alcohol-containing blood (Landolfi and Steiner, 1984).

Leukotriene B_4 (LTB_4) is an inflammatory mediator produced from arachidonic acid via 5-lipoxygenase enzyme activity (Ford-Hutchinson, 1985). As with $PGF_{2\alpha}$, LTB_4 is a potent chemotactic agent (Paulissen et al., 1990; Van de Kerkhof et al., 1991) and may also be a potent vasodilator and cause significant increases in vascular permeability when coadministered with PGE_2 (Ford-Hutchinson, 1985). Although LTB_4 is most commonly produced by leukocytes, skin contains some inherent 5-lipoxygenase activity as determined from studies using stimulated human keratinocytes in culture as well as human and murine epidermal homogenates (Ruzicka, 1990). These inflammatory mediator-induced changes in cutaneous blood flow may impact on the absorption and cutaneous distribution of topically applied drugs.

Protein Metabolism

The primary protein product of the skin is keratin, which is the main intracellular component of the stratum corneum. In tandem with extracellular lipid, keratin forms the major component of the epidermal barrier. Keratin primarily consists of cystine, serine, glutamic acid, arginine, aspartic acid, and glycine amino acid residues. Of significance within the keratin molecule structure is the intrachain cystine disulfide bridging that further strengthens the overall keratin macrostructure. Keratin is the major protein foundation of hair (Monteiro-Riviere, 1991, 2006).

Principles of Percutaneous Absorption: Skin Permeability

Prior to the 20th century, many scientists believed that skin was an impermeable barrier to all substances, except possibly gases. The science of dermatology has since advanced to reveal that many substances can enter the systemic circulation via the skin. Four pathways by which substances can gain this access to the rest of the body have been postulated and are schematically shown in Figure 47.2.
